Energy Aware Deep Reinforcement Learning Scheduling for Sensors Correlated in Time and Space

Jernej Hribar, Andrei Marinescu, Alessandro Chiumento, and Luiz A. DaSilva

Abstract

Millions of battery-powered sensors deployed for monitoring purposes in a multitude of scenarios, e.g., agriculture, smart cities, industry, etc., require energy-efficient solutions to prolong their lifetime. When these sensors observe a phenomenon distributed in space and evolving in time, it is expected that collected observations will be correlated in time and space. In this paper, we propose a Deep Reinforcement Learning (DRL) based scheduling mechanism capable of taking advantage of correlated information. We design our solution using the Deep Deterministic Policy Gradient (DDPG) algorithm. The proposed mechanism is capable of determining the frequency with which sensors should transmit their updates, to ensure accurate collection of observations, while simultaneously considering the energy available. To evaluate our scheduling mechanism, we use multiple datasets containing environmental observations obtained in multiple real deployments. The real observations enable us to model the environment with which the mechanism interacts as realistically as possible. We show that our solution can significantly extend the sensors’ lifetime. We compare our mechanism to an idealized, all-knowing scheduler to demonstrate that its performance is near-optimal. Additionally, we highlight the unique feature of our design, energy-awareness, by displaying the impact of sensors’ energy levels on the frequency of updates.

I. INTRODUCTION

Millions of low-power devices are being deployed to provide services in smart cities [2], Industry 4.0 [3], smart agriculture [4], and other Internet of Things (IoT) applications. Many of these devices are low-cost sensors powered by non-rechargeable batteries. Their role is to provide sensed information to services, which use this information to make decisions. For example, in smart agriculture, a service controlling an irrigation system requires information from various sensors to decide which fields to water. The main challenge is to provide accurate and up-to-date information to services while keeping the deployments of battery-powered devices functional for as long as possible.

In a system of multiple sensing devices observing the same physical phenomenon, it is expected that the information collected will be correlated in time and space. By relying on this correlation, we have shown that it is possible to increase the time between consecutive updates by each sensor, thereby increasing its lifetime, without compromising the accuracy of the information provided to the IoT service [5]. In the absence of up-to-date information from one sensor, the system can rely on more recent information obtained from a correlated sensor. In this paper, we propose a Deep Reinforcement Learning (DRL)-based scheduling mechanism capable of determining how frequently each low-power sensor should transmit its observations so as to furnish the service with accurate information while maximising the lifetime of the network.

We consider an IoT system where low-power sensors transmit periodic updates to a gateway. The gateway is able to schedule when the next update by each sensor should occur. The gateway relies on a data-driven approach to make this determination, by considering the energy available to each low-power sensor and the need for fresh updates, according to concepts related to the Age of Information (AoI) [6]. We design a DRL solution capable of learning from past experiences.

Multiple, often non-trivially connected, factors impact the decision of when a particular low-power sensor should transmit new information. These factors can be external to the sensor, such as whether a nearby sensor has recently transmitted updated information, changes in the observed physical phenomenon, etc., or internal to the sensor, e.g., the remaining energy, transmission power, or location. The use of DRL enables us to design a scheduling mechanism capable of
determining when sensors should transmit updated sensed information to a gateway, by weighing all relevant factors to make an efficient decision.

In this paper, we use DRL to improve the energy efficiency of low-power sensors by leveraging the correlation exhibited in the information they collect. In particular, we make the following contributions:

- The main contribution of this paper is the design of a DRL energy-aware scheduler that is capable of determining when an IoT sensor should transmit its next observation. We make use of Deep Deterministic Policy Gradient (DDPG), a DRL algorithm, to arrive at an efficient transmission schedule for sensors based on their available energy, the freshness of the information collected, and the expected lifetime of all other sensors in the network, without compromising the accuracy of the information delivered to the application.

- A unique feature of our solution is energy balancing. Our mechanism is capable of determining to what extent the energy available to one sensor can be used to prolong the lifetime of others. We benchmark our solution by comparing it to an ideal scheduler that acts as an oracle and is assumed to know the ground truth about the phenomenon being observed.

- To validate our solution, we use more than five different datasets to demonstrate its near-optimal performance in a variety of scenarios. Note that we leverage real data to model the environment in which our scheduler operates as realistically as possible.

After briefly reviewing the relevant literature in Section II, in Section III we describe how a system of sensors collecting correlated information can estimate the accuracy of their observations. We describe the decision-making problem that our proposed scheduling mechanism is capable of assisting with in Section IV. We present how we incorporated DDPG into our proposed mechanism (Section V A), describe the system dynamics using states, actions, and rewards from a Reinforcement Learning (RL) perspective (Section V B), and provide implementation details (Section V C). We utilize data obtained from real deployments to show that the learned behaviour significantly prolongs the sensors’ lifetime and achieves near-optimal performance (Section VI A). Additionally, we demonstrate the scheduling mechanism’s energy awareness when deciding on the sensors’ transmission times (Section VI B). Finally, we summarise our main findings and discuss our future work in Section VII.
II. RELATED WORK

Our work leverages the recently proposed AoI metric [7], which quantifies the freshness of information. The AoI metric measures the time since a status update generated by a source, e.g., a sensor, was last received. Each status update contains the latest information collected by the source and a timestamp. The more recently the status update was generated, the more relevant it is to the decision process. Finding the optimal update rates with which sources should send information is non-trivial [8], and considering correlation between status updates adds to the complexity of the problem, as an update from one source lowers the requirement for fresh information on all other correlated sources. We were the first to propose taking advantage of fresher information from correlated sources to improve the energy efficiency of battery-powered sources by prolonging the times between sources’ consecutive updates [5]. Subsequently, the authors in [9] and [10] analyzed from different perspectives a system with correlated sources. In [9], the authors consider a system in which multiple sources may observe the same information captured by sensors, i.e., multiple sources can obtain the same status update. In [10], the authors considered a one-dimensional static random field from which multiple sources transmitted observations. The works in [5], [9], [10] considered only the impact of correlation on the timeliness of information to establish the desired frequency of updates. This paper presents a solution that considers both the timeliness of the information and the energy available to the sources to arrive at a scheduling of information updates that improves network-wide energy efficiency.

Our work is also related to, but differs in crucial aspects from, the various approaches proposed for energy efficiency in the context of wireless sensor networks (WSNs) [11]–[15]. Most proposed works for WSNs rely on detection or reconstruction of the observed phenomena, through data prediction or model-based active sampling methods, to improve the low-power sensors’ energy efficiency. In contrast, we focus on the timeliness of updates, and in particular the AoI, and then employ RL to determine how to utilize correlated measurements to reduce the rate at which sources transmit their updates.

RL has been applied to other energy-aware networking solutions [16]–[25]. For example, in [17] the authors use Q-learning to enhance the spectrum utilization of industrial IoT devices. They demonstrate that devices are capable of learning a channel selection policy to avoid collisions, thus reducing retransmissions. The authors in [23] propose a channel-state aware scheduling
mechanism using a Deep Q-Network (DQN) that enables a device to learn when to transmit and which channel to use for transmission. The authors in [18] investigate the use of a semi-supervised DQN to improve indoor users’ location estimation by leveraging information on Bluetooth signal strength. The work in [20] relies on a no regret RL approach, while the authors in [21] apply an actor-critic algorithm to analyse how an energy-harvesting device will collect energy and schedule its transmissions accordingly. In both cases, the objective is more effective power management, using RL to prevent power outages, i.e., to avoid the situation where an energy-harvesting device completely depletes its energy. The power control in an energy harvesting system is also investigated in [25]. The authors, using a multi-agent approach (with a DQN algorithm), designed a distributed power control mechanism that maximises devices’ throughput. The authors in [24] use a DQN algorithm to solve a task offloading problem for vehicles. Their solution is capable of saving energy by selecting more efficiently where in the edge a task from a vehicle should be processed. In [22], the authors apply a deep belief neural network to design a data recovery mechanism for sensors that collect spatio-temporally correlated information. Their mechanism is capable of determining which observations from other sensors could be used to replace missing or corrupted observations.

In [1], we first introduced a variant of the proposed scheduling mechanism. In this paper, we extend our work by designing an improved DRL-based mechanism (based on a DDPG algorithm, while [1] relied on a DQN algorithm) and providing a comprehensive evaluation of the effectiveness of our solution. We compare our solution to one conventional way of setting the sensors’ update intervals, and to the optimal scheduler we designed specifically for evaluation purposes. Furthermore, we test our mechanism over three additional real-world datasets. Another extension of our work is in providing new results that demonstrate the energy balancing aspect of our solution.

III. QUANTIFYING THE ACCURACY OF OBSERVATIONS

We consider a sensor network with \( N \) geographically distributed sensors transmitting observations to a gateway for collection. The main purpose of these sensors, denoted as \( \{S_1, \ldots, S_N\} \), is to observe a physical phenomenon \( Z(X, t) \) distributed in space \( X \) and evolving in time \( t \). Sensors are deployed at positions \( X_n \) and transmit periodic observations with an update.

\(^1\)We perform the physical modeling of the observed phenomenon using observations obtained in a real IoT deployment [26], [27].
Fig. 1: A system of $N$ randomly distributed sensor nodes, whose observations are used to estimate the value of observed physical phenomenon, $Z(X, t)$, at location $X_i$ at time $t$.

interval $T_n, n = 1, \ldots, N$. In our system, we assume that the latest received observation from a sensor replaces the previously received information as, according to the AoI paradigm, the freshest information is the most relevant in the decision making process [7]. Whenever the system receives an observation from location $X_n$ at time $t_n$, the system will anticipate the arrival of the next observation from location $X_n$ at time instance $t = t_n + T_n$. We write the collected observations into a vector $Y = [y_1, \ldots, y_N]^T$ with $y_n = Z(X_n, t_n)$ where $t_n$ is the latest time at which sensor $n$ has reported an observation.

The system can estimate the value of the observed physical phenomenon at the desired location $X_i$ at any time instant $t$ using the collected information, as presented in Fig 1. We denote the Euclidean distance between sensor $S_n$ and the location of interest $X_i$ as $d_{n,i}$. With $\Delta_{n,i}(t)$ we denote the time elapsed since the system received the latest observation from sensor $S_n$, i.e., the AoI, $\Delta_n(t) := t - t_n$. Using every available observation, we apply a Linear Minimum Mean Square Error (LMMSE) estimator as in [28], to estimate the observed physical phenomena using correlated observations. This approach offers a mathematically tractable way of estimating the value of the observed phenomena and the resulting estimation error. We can approximate the value of the observed physical phenomenon at position $X_i$ at time instant $t$, as:
\[
\hat{y}_i(t) = \sum_{n=1}^{N} w_{n,i}(t) y_n,
\]  
(1)

where \( w_n(t), n = 0, \ldots, N \) are LMMSE estimator weights.

Following the analysis in [29], we obtain the LMMSE estimator weight vector \( W_i(t) = [w_{0,i}(t), \ldots, w_{N,i}(t)]^T \) as follows:

\[
W_i(t) = \left( C_{YY}(t) \right)^{-1} c_{i,YZ}(t).
\]  
(2)

The matrices \( C_{YY}(t), c_{i,YZ}(t) \) are covariance matrices, required to determine \( W_i(t) \):

\[
C_{YY}(t) = \begin{bmatrix}
    C_{1,1}(t) & \cdots & C_{1,N}(t) \\
    \vdots & \ddots & \vdots \\
    C_{N,1}(t) & \cdots & C_{N,N}(t)
\end{bmatrix};
\]
\[
c_{i,YZ}(t) = \begin{bmatrix}
    C_{i,1}(t) \\
    \vdots \\
    C_{i,N}(t)
\end{bmatrix};
\]  
(3)

in which \( C_{j,k}(t); j, k = 1, \ldots, N \), is the covariance of observations \( y_j \) and \( y_k \), and \( C_{j,i}(t) \) is the covariance of \( y_j \) and the observed process \( Z \) at the desired location of the estimation. To obtain the required matrices we can rely on a covariance model and utilize past observations to determine its values. We adopt a separable covariance model defined in [30]. With it we model how observations collected at different instants in time and different locations relate to each other. We express the covariance between two observations or one observation and the estimation point, with time difference \( \Delta_{j,k}(t) \) and distance \( d_{j,k} \) apart as:

\[
C_{j,k}(d_{j,k}, t|\theta_1(t), \theta_2(t)) = \exp(-\theta_2(t) d_{j,k} - \theta_1(t) \Delta_{j,k}(t)).
\]  
(4)

Note that \( \theta_1(t) \) and \( \theta_2(t) \) are scaling parameters of time and space, respectively. With \( d_{j,k} \) we denote the Euclidean distance between sensor \( S_j \) and the location at which the system estimates the value of the observed physical phenomenon, or between sensor \( S_j \) and sensor \( S_k \). Both scaling parameters change over time and are extracted from the obtained observations. In our work, we follow a scaling extraction method with Pearson’s correlation coefficient formula for samples, as described in [31].

The selected covariance function provides a good fit to model spatial and temporal variation for many physical phenomena. For example, in [30], the authors showed that such a covariance model could be applied to wind-speed data. We demonstrated in [5] that the selected model is applicable to the temperature and humidity sensor data used in the evaluation section. Additionally, such
spatio-temporal correlation can be observed in many IoT sensor deployments: examples include IoT systems in a smart city measuring air pollution, precipitation, or noise [2], and smart farm applications in which an IoT system monitors soil parameters [4].

Every time the system employs Eq. (1) to estimate the value of the observed physical phenomenon it makes an error. By using matrices $C_{YY}(t)$ and $c_{YZ}(t)$ it is possible to determine the Mean Square Error (MSE) in the estimation as:

$$
\varepsilon_i(X_i, t | \theta_1(t), \theta_2(t)) = \sigma^2_Z - c_{ZY}(t)W_i(t),
$$

where $c_{ZY}$ is the transpose of $c_{YZ}$ defined above, and $\sigma^2_Z$ represents the variance of the observed phenomenon. The estimation error provides a measure with which the gateway can quantify the quality of the information currently provided by the sensing process: the lower the value of the estimation error, the more accurate the estimated values and the lower the need for an additional update. Hence, by measuring the average estimation error between two consecutive updates the gateway can assess how accurate and up-to-date the observations collected by the system are. In our work, we control the accuracy of our sensing process by setting as a constraint the maximum MSE of the estimator, $\varepsilon^*$. In short, the purpose of our proposed updating mechanism is to set sensors’ update intervals in such a way that the average estimation error will not exceed the set target. In the next section, we describe the optimisation problem that the gateway must solve: maximising the network lifetime, constrained by the target accuracy in the measurements.

**IV. PROBLEM FORMULATION**

The scenario of interest to our work is the use of inexpensive battery-powered sensors, transmitting observations to a gateway for collection. The gateway aims to schedule the transmission of observations in such a way that the accuracy of the information collected will satisfy the service requirements, i.e., average estimation error below $\varepsilon^*$, while, simultaneously, trying to prolong the lifetime of the deployed sensor network. Whenever a sensor transmits an observation, the updating mechanism residing in the gateway decides on the low-power sensors’ next update time by evaluating the accuracy of collected observations and the sensors’ available energy. Each sensor’s lifetime depends on the frequency of transmitted observations, i.e., the time between two consecutive updates, and on the continuous power consumption, which is independent of transmissions.
In this work, we assume that a non-rechargeable primary battery powers the low-power sensors. Therefore, we can model a sensor’s lifetime $L_n(T_n)$ as in [32]:

$$L_n(T_n) = \frac{E_0}{P_c + \frac{E_{tr}}{T_n}},$$

where $E_0$ represents the sensors’ starting energy and $P_c$ is the continuous power consumption, and $E_{tr}$ represents the energy required to acquire and transmit the observation. The continuous power consumption is the power that the sensor requires to function regardless of mode of operation and depends solely on the sensor hardware components. For low-power IoT sensors, $P_c$ is in the range of a few $\mu W$ or less. The energy required to transmit the observation, i.e., $E_{tr}$, depends on many factors such as the size of the transmitted packet, the energy required to take the measurement, and channel conditions.

Energy is not the only factor the updating mechanism has to take into account. As described in [33], low-power sensors are also constrained in terms of available computing power, memory, communication capabilities, etc. Limited processing power and memory prevent the use of a sophisticated algorithm on the sensor itself. Therefore, computationally demanding tasks when making a decision should be carried out at the gateway. Additionally, these sensors rely on low data rate transmission, meaning that communication messages between sensors and gateway should be kept to a minimum. Furthermore, to extend their lifetime, low-power sensors rely on the use of sleep mode. When a sensor is in sleep mode, the rest of the network cannot communicate with it. Consequently, the gateway has to inform each sensor, while the sensor is still in active mode, when it should wake up again and transmit the next observation. Sleep mode is supported by most Low-Power Wide-Area Network (LPWAN) standards, such as SigFox, Weightless, Long Range Wide Area Network (LoRaWAN)$^2$, and Narrowband IoT (NB-IoT) [34]. The low-power sensor is usually in active mode only after it has transmitted. For example, a sensor using a LoRaWAN class A radio will listen for two short time-windows after it has transmitted, as illustrated in the LoRaWAN message sequence in Fig. 2 [35], meaning that the updating mechanism only has a short time-window to provide a response.

The gateway’s goal is to prolong the network lifetime. We define the network lifetime as the lifetime of the sensor with the shortest lifespan in the deployment. In other words, the network

---

$^2$For more information, the reader may visit http://www.sigfox.com; http://weightless.org; http://www.lora-alliance.org, respectively.
lifetime expires the moment one sensor depletes all of its energy. To that end, the gateway should aim to minimise transmissions by all sensors, i.e., increase $T_{n}$, and, when updates are required, favour sensors with higher remaining energy, all while keeping the average estimation error of the observed physical phenomenon at every location of interest below the pre-specified value, i.e., $\varepsilon^*$. In a real deployment, services dictate which locations are of interest for the system. In this paper, we consider every sensor location, i.e., $X_{n}$, to be a location of interest, meaning that the system has to make accurate estimations at the location of every sensor while keeping sensors’ power consumption to a minimum. We summarise the decision-making process in Fig. 3. The gateway decides on each sensor’s next update time by evaluating the accuracy of the collected observation and the sensors’ available energy, which it can determine from the sensor’s reported power supply measurement. The gateway can then decide when the sensor should transmit its next observation.

Transmission from a sensor $\hat{n}$ starts the decision-making process at time $t_{\hat{n}}$: due to the energy-constrained nature of the devices, the gateway has a limited time to determine the sensor’s next update time, i.e., determine for sensor $\hat{n}$ a new sensor update interval $T_{\hat{n}}$. In practice, the gateway usually has around one second to reply with the new update interval. Further, we discretise the
possible update intervals in steps of duration $t_S$, up to a maximum update interval of $T_{\text{max}}$, an integer multiple of $t_S$. Discretising time enables us to formulate the problem the gateway faces as follows:

$$\maximize_{\hat{T}_n} \min \left( \mathcal{L}_n(T_n) \right), \forall n = 1, \ldots, N$$

subject to $\varepsilon_n(t_{\hat{n}} + \hat{T}_n) \leq \varepsilon^*, \forall n = 1, \ldots, N,$

$$T_{\hat{n}} \in \{t_S, 2t_S, \ldots, T_{\text{max}}\}.$$  \hspace{1cm} (7)

At time step $t_{\hat{n}}$, when the gateway receives an observation from sensor $\hat{n}$, the gateway has to select the update interval $\hat{T}_n$ that will maximise the lifetime of the sensor (or sensors) in the deployment with the shortest life expectancy. At the same time, the accuracy constraint has to be met for all sensors for the entire time duration until the next update is received. Note that the update time for one sensor potentially affects the lifetime of all other sensors.

To solve the problem, the gateway could turn to a numerical solver. However, due to the matrix inversion in Eq. (2), required to determine the MSE value using Eq. (5) for $N$ sensors, the expected computational complexity to solve the proposed problem is of the order of $O(N^4 T_{\text{max}} t_S)$. With computational complexity rising to the power of four with the number of sensors, the gateway, in practice, does not have enough time available to determine the sensor's new update interval.

The system is highly dynamical, as each received observation impacts the covariance model's scaling parameters. As a result, the value of the MSE (Eq. (5)) continuously varies over time. Intuitively, when a sensor has more energy available than others, it should transmit more often, to enable other sensors (which will transmit in the future) to increase their update intervals. Such a problem is ideal for a RL approach because the agent (in our case the gateway) can learn how to take actions that might bring negative reward in the near future but will ultimately increase the long-term reward [36] in prolonging the network lifetime. In the next section, we show how we model the decision making discussed using an RL solution, describing the relevant states, actions, and rewards. Then, by applying a DDPG algorithm, the gateway can arrive at a long-term updating policy to collect accurate observations and prolong the network lifetime.

V. Deep Reinforcement Learning Approach

In DRL, the agent learns its optimal behaviour, i.e., the best long term action to be taken in every state, from interactions with the environment. In our case, the learning agent resides in
the gateway. The agent follows a sequence of events. Once a sensor transmits an update, the agent has to respond by setting the sensor’s update interval, and by calculating the MSE value it can assess the impact of the set update interval. The agent must also consider the remaining energy available in each battery-powered sensor and their current update intervals when making the decision. To solve the decision-making problem the agent is facing, we selected a DDPG algorithm, which enables us to design a scheduling mechanism with a high number of possible actions regarding setting the sensor’s update interval. There are two main advantages of using a DDPG algorithm over other DRL algorithms: 1) there is a high convergence guarantee even when using non-linear function approximations, e.g., Artificial Neural Network (ANN) [37] and 2) DDPG is deterministic, meaning that the policy gradient is integrated only over the state space, thus requiring much fewer samples to find the optimal policy in comparison to stochastic algorithms [38]. In our work we follow the DDPG algorithm implementation as presented in [39].

A. Deep Deterministic Policy Gradient Algorithm

DDPG is an actor-critic algorithm and, as the name suggests, consists of two entities/Artificial Neural Network (ANN): the actor taking actions, and a critic that evaluates them. The critic is implemented as a DQN and we denote its ANN as $Q(s, a|\theta^Q)$ where $\theta^Q$ are weights of the critic’s ANN, with $a$ denoting the action the agent takes in state $s$. Next, we define the actor as a parametric function $\mu(s|\theta^\mu)$ in which $\theta^\mu$ represents the actor’s ANN weights. In addition, during the training process we initialize the target ANN $Q'(s, a|\theta^Q')$ and $\mu'(s|\theta^\mu')$ with weights $\theta^Q'$ and $\theta^\mu'$ for critic and actor respectively. The agent selects actions according to its current policy with added noise $a = \mu(s|\theta^\mu) + \mathcal{N}$, where $\mathcal{N}$ represent added random noise. Note that exploration in a DDPG algorithm is carried out by adding a random value, i.e., noise, to the actor’s selected value. Then the agent transitions into a new state $s'$ and receives reward $r$. The transition $(s, a, r, s')$, also referred to as experience, is stored in memory. When the algorithm is training the ANN it first samples a mini-batch of $M$ experiences from the batch and calculates the target values:

$$h_m = r_m + \gamma Q'(s'_m, \mu'(s_m|\theta^\mu')|\theta^Q'),$$

with $m$ denoting the selected experience from the batch. After determining $h_m$ we can update the critic by minimizing the loss $L$ as:

$$L = \frac{1}{M} \sum_{m=1}^{M} (h_m - Q(s_m, a_m|\theta^Q))^2.$$
With the loss function calculated, the algorithm then updates the actor’s policy using the sampled policy gradient:

$$\nabla_{\theta} J \approx \frac{1}{M} \sum_{m=1}^{M} \nabla_a Q(s, a|\theta^Q)|_{s=s_m, a=\mu(s_m)} \nabla_{\theta} \mu(s|\theta^\mu)|_{s_m}. \tag{10}$$

In the last step the DDPG algorithm updates the target ANNs:

$$\theta^Q' \leftarrow \tau \theta^Q + (1 - \tau_C) \theta^Q', \tag{11}$$
$$\theta^\mu' \leftarrow \tau \theta^\mu + (1 - \tau_A) \theta^\mu', \tag{12}$$

where \(\tau_A\) and \(\tau_C\) represent the target networks update factor. Note that the role of the target ANNs is to calculate \(h_m\). Using separate target networks along with the replay buffer provide stability during the training process as was established in [40].

Figure 4 illustrates how we adopt DDPG in our scheduling algorithm. In our approach, the gateway performs every computationally demanding task. A low-power sensor only receives a command message that instructs the sensor for how long it should enter sleep mode. By setting the duration of each sensor’s sleep mode, the gateway effectively schedules the sensors’ transmission of updates. In our mechanism the actor’s actions are limited to increasing and decreasing the sleep time, and the critic’s role is to evaluate whether the selected change is beneficial to the system. The critic derives a value representing the quality of the selected action using the reward for the actor. The actor then uses the provided quality of action value to adapt its policy accordingly.
Next, we define states, actions, and rewards, i.e., a tuple in \( \langle S, A, R \rangle \) that enables the gateway to determine each sensor’s optimal update interval.

B. States, Actions, and Rewards

For each sensor, the state \( s_n \in S \) must capture three critical aspects of the decision-making process in the gateway: a sensor’s current update interval, its available energy, and the value of the estimation error. Whenever a sensor \( n \) transmits an observation, the gateway stores the information regarding the sensor’s update interval, \( T_n \), available energy, \( E_n \), and the value of the average MSE since the last transmission, \( \bar{\varepsilon}_n \). The inclusion of these three pieces of information from every sensor would result in an overly complex state space: we therefore turn to the geometric mean to compress the number of state inputs. The state \( s_n \) can be expressed as a six-dimensional vector:

\[
 s_n = (T_n, E_n, \frac{\bar{\varepsilon}_n}{\varepsilon^*}, \left( \prod_{i=1, i \neq n}^{N} T_i \right)^\frac{1}{N-1}, \left( \prod_{i=1, i \neq n}^{N} E_i \right)^\frac{1}{N-1}, \left( \prod_{i=1, i \neq n}^{N} \frac{\varepsilon_i}{\varepsilon^*} \right)^\frac{1}{N-1})
\]

with \( N \) representing the total number of sensors under the agent’s control. The learning agent always interprets states from the perspective of the sensor that has transmitted an observation, and for which it is making the decision. The first three inputs correspond to the transmitting sensor’s update interval, available energy, and the ratio between MSE and target estimation error. Relying on the ratio enables the learning agent to perform well even if the target estimation error changes, as we demonstrate in the next section. Using the geometric mean enables us to reduce the number of state inputs, while simultaneously making sure the learning agent captures the most significant information about the environment. For example, the geometric mean provides information to the agent regarding whether the energy level in the majority of the sensors is low or high.

The learning agent’s action is limited to either increasing or decreasing the sensors’ current update interval. In our implementation, the action value \( (a_n \in A) \) returned by the DDPG algorithm is between \(-1\) and \(1\), i.e., \( A = [-1, 1] \). To determine the sensors’ new update interval, we multiply the received action value by a constant, representing the selected maximum update interval change \( U_{max} \). We calculate the new update interval as follows:
\[ T_n = \min \left( \max \left( T_n + \left\lfloor U_{max} a_n \right\rfloor, 1 \right), T_{max} \right), \quad (14) \]

where \( T_n \) is the sensors’ previous update interval. Note that the value of \( U_{max} \) can be relatively large, e.g., hundreds of seconds, and our approach will still perform well.

We form the reward with the learning agent’s goals in mind. The learning agent has to ensure that information collection is frequent enough to maintain the freshness of the information and simultaneously try to prolong the sensors’ lifetime. We express the reward as:

\[ r_n(\varepsilon_n, E_n) = \phi r_{acc}(\varepsilon_n) + (1 - \phi) r_{en}(E_n). \quad (15) \]

\( r_{acc}(\varepsilon_n) \) is the reward for accurate collection of observations and \( r_{en}(E_n) \) is the reward related to the energy aspect of the problem. The weight \( \phi \in [0.25, 0.75] \) controls the balance between the reward for accurate collection of observations and the sensors’ energy preservation. We restrict the range of the weight \( \phi \) to avoid the reward from being overly weighted towards one goal or the other.

The accuracy reward depends on whether the set average accuracy, \( \varepsilon^* \), was satisfied since the \( n \)-th sensor’s last transmission, as well as on the change in the estimation error since the last transmission. We define the accuracy reward as:

\[ r_{acc}(\varepsilon_n) = \begin{cases} 
(\varepsilon_n - \varepsilon^*)^2 + \Upsilon \Delta \varepsilon_n & \text{when } \varepsilon_n \leq \varepsilon^* \\
(\varepsilon_n - \varepsilon^*)^2 - \Upsilon \Delta \varepsilon_n & \text{when } \varepsilon_n > \varepsilon^* 
\end{cases} \quad (16) \]

where \( \Delta \varepsilon_n \) represents the change in the average estimation error since the previous transmission. The closer the estimation error is to the target, the greater will be the reward from the first term of the expression. The second term of the accuracy reward steers the learning agent towards keeping the MSE as close as possible to the target \( \varepsilon^* \), without exceeding it. The factor \( \Upsilon \) is used to balance the contributions of the two parts of the accuracy reward.

Our energy reward exploits the relationship between the update interval and a battery-powered sensor’s lifetime. The longer the time between the consecutive updates, the longer the sensors’ lifetime will be. Therefore, the selected energy reward is based on how the update interval is increased or decreased, as follows:
\[ r_{en}(E_n) = \begin{cases} 
1 - \frac{N E_n}{\sum_{i=1}^{N} E_n}, & \text{if } T_{\hat{n}} > T_n \\
0, & \text{if } T_{\hat{n}} = T_n \\
\frac{N E_n}{\sum_{i=1}^{N} E_n} - 1, & \text{if } T_{\hat{n}} < T_n
\end{cases} \]  

(17)

where \( E_n \) is the sensor’s available energy. If a sensor has above average available energy, the energy reward should encourage the learning agent to make sure that such a sensor updates more often, and vice-versa if a sensor has below average energy.

In the next subsection, we present our implementation of the DDPG algorithm.

C. Artificial Neural Network Structure

To implement the learning agent using DDPG as described in [39] we used Pytorch [41], a standard Python-based library for implementing DRL algorithms. We employ similar ANN structures for the actor and the critic. The actor’s ANN consists of an input (state space), output (action value), and four hidden layers with Feedforward Neural Network (FNN) structure, as shown in Figure 5. We use 75 neurons in the first three hidden layers and 25 neurons in the fourth layer. Between each hidden layer, we implemented a 50% dropout layer. We use batch normalization after activation in the first hidden layer. The dropout layers prevent over-fitting, and batch normalization improves the learning speed. We employ the same structure for the critic’s ANN, with a slight difference in the activation function used. We use a ReLU activation function for every layer in both ANNs. The only exception is the output layer of the actor’s ANN, where we use a Hyperbolic function. Such a difference is required as the actor’s output value is limited to values between \(-1\) and \(1\) while the critic’s is not. To train the ANNs we periodically perform batch learning. In each batch training we use 128 experiences. Each experience consists of a state, corresponding action and reward, and the state to which our sensor transits after taking the selected action. Note that 128 experiences are randomly selected from a memory pool of up to 100,000 experiences.

In the gateway we deploy only one set of actor’s and critic’s ANN for the DDPG algorithm to control the update times of all \(N\) sensors in the deployment. Upon the \(n\)-th sensor’s transmission the gateway constructs the state input from its perspective. The first three inputs to the ANN represent the \(n\)-th sensor information (current update time, average estimation error, and energy), and the last three inputs represent the information from every other sensor in the deployment as
Following such an approach, we can extrapolate the knowledge obtained from one sensor behavior to all others.

We set the start of an episode to when a sensor transmits an observation. When the gateway receives an observation, it uses the interpreter to determine the sensor’s state and calculates the reward for the action taken, i.e., the change in the update interval. The sensor state information is then passed to the learning agent to determine the new action; the learning agent calculates the sensor’s new update interval and informs the sensor. The sensor will enter sleep mode for the amount of time determined by the learning agent. As soon as the sensor wakes up, the episode ends, and the new episode starts as the sensor transmits a new update. Note that multiple episodes happen in parallel, one for each sensor under the mechanism’s control. While one sensor is in sleep mode, another wakes up and transmits an observation. Exploration in DDPG algorithms is performed by adding noise, i.e., a random value, to the actor’s output value. We use the Ornstein-Uhlenbeck process [39] to generate a random value to be added to the selected action value.

The agent has limited time available to decide on the sensor’s new update interval. In the previous section, we established that the computational complexity of the optimisation problem increases with the number of sensors to the power of four. The computational complexity of
our DRL solution, on the other hand, depends solely on the dimension of the action space, $D_a$, the dimension of the state space, $D_s$, number of layers $L$, and the number of neurons in each hidden layer, $W$. Each invocation of forward propagation, i.e., when the agent makes its decision, is linear with respect to the ANN parameters. This means that we can write the number of computations required for the actor as $O(D_s LW)$, and, similarly, as $O((D_a + D_s)LW)$ for the critic. Considering that we employ ANNs with only four hidden layers, i.e., $L=4$, and with 75 neurons (25 in the fourth hidden layer) per layer the resulting number of computations is relatively small and our agent is capable of responding within 2 to 3 ms, thus satisfying the timing constraints set by the sensors’ communications technology. For comparison, the same system would need 7-12 seconds for $N = 10$ to resolve the optimisation problem numerically. Furthermore, while for a numerical solution to the optimisation problem the complexity rises with number of sensors to the power of four, in our DRL approach the input state space $D_s$ does not depend on $N$.

In the next section, we evaluate the performance of our proposed mechanism using data obtained from a real sensor network deployment.

VI. Evaluation and Results

In this section, we evaluate our proposed scheduling mechanism using observations provided by the Intel Berkeley Research laboratory [26], as well as data collected from multiple sensors deployed in the city of Santander, Spain, as part of the SmartSantander testbed [27]. In our experiments, a simulated sensor transmits an observation with the exact value as was obtained by its real world counterpart. In other words, the data enables us to realistically represent how the observed physical phenomenon varies over time. We evaluate our mechanism using five different datasets: two from Intel (temperature and humidity), and three from SmartSantander (temperature, humidity, and ambient noise). We split the evaluation into two parts: In the first part, we demonstrate that the proposed scheduling mechanism is capable of learning the optimal behaviour and that using our approach can significantly extend the sensors’ lifespan. In the second part of our evaluation, we highlight the energy-aware aspects of our proposed scheduling mechanism.

Each simulated sensor is assigned observations obtained by a real sensor. When our simulation determines that a particular sensor has to transmit an observation, the gateway receives a measurement which the simulated sensor real counterpart has obtained in the corresponding
time moment. Additionally, we use sensor locations as they were in real deployments. The Intel laboratory dataset provides observations collected over nine days of measurements from 50 sensors. The Intel data comprises observations collected very frequently (every 31 seconds), providing us with a ground truth of observed values for the evaluation process. On the other hand, the Smart Santander data represents a realistic deployment of sensors in a smart city environment. In our analysis, we use data obtained in the first nineteen days of April 2018. We rely on data from twenty temperature, ten humidity, and eight ambient noise sensors. In contrast to the Intel data, every sensor transmitted observations at different time intervals, and sometimes there were a few hours during which a sensor did not send any observation. We use the Amelia II software program [42], a tool to generate missing data, to produce the missing values. To generate these values, we used observations from the sensor that collected the highest number of observations; as a consequence, we had to remove that sensor from each SmartSantander dataset, to avoid adding bias in the evaluation.

Due to our use of real observations to model the environment, we had to insert an extra step at the evaluation stage. The learning agent could recognise patterns in the collected observations and adapt its behaviour accordingly. In other words, the agent could overfit its policy to the dataset. To avoid such a scenario, we have to ensure that the environment the agent interacts with during evaluation is new. To that end, we had to split each dataset into two parts. The first part is used for exploration, during which the agent learns the policy. The second part is used for the evaluation of its performance. We split the Intel dataset into six days used for exploration and three days for evaluation, while for SmartSantander we use the last six days for evaluation and the rest to train the agent.

We list system parameters that are kept constant throughout our evaluation process in Table...
I. We selected static simulation energy parameters by assuming that each of the sensors is powered by a single non-rechargeable Lithium coin battery with a capacity of 620 mAh, which provides us with the value for $E_0$. The selected energy consumption parameters, i.e., $P_c$ and $E_{tr}$, mimic the power consumption of an IoT sensor using a LoRaWAN radio. We obtain the power parameters following the analysis presented in [43]. The selected $U_{max}$ yielded the best average performance at the end of the training phase for all five datasets. $T_{start}$ represents a suitable starting update time value, while $T_{max}$ represents the maximal value that should be allowed between two consecutive updates from one sensor. At the start of every simulation, we set the same initial update time for every sensor. $\phi$ and $\epsilon^*$ are set to the value stated in the Table unless they are parameters that we change in the presented experiment. We perform simulations in ten-second time-steps. In Table II we list the DRL solution hyperparameters we determined through a grid search to be most suitable. Note that we multiply the calculated rewards by a factor of 10 to improve the training process, as higher reward values tend to reduce the time required for the DDPG algorithm to arrive at the optimal policy [44].

A. Performance Evaluation

In this subsection, we evaluate our scheduling mechanism’s ability to maintain accurate observations and compare it to other scheduling approaches.

First, we test the updating mechanism performance as the number of sensors, $N$, under its management increases. The Intel datasets offer us a maximum of 50 sensors, and for cases in which $N < 50$, we randomly selected a subset of these sensors and then repeated the experiment several times. As expected, increasing the number of sensors leads to more correlated information available, and therefore, the gain of using correlated information increases with the number of sensors. The benefit of using correlated information is higher when observing temperature, due to higher correlation exhibited in the observations collected. We calculate the expected lifetime using Eq. (6). In Fig. 6(a) we use both Intel datasets, humidity and temperature, and calculate the expected lifetime using the average update interval that sensors achieved in the experiment. Additionally, to demonstrate the performance improvement brought by our solution, we calculate the lifetime gain $\eta$, plotted in Fig. 6(b). We define this gain as the ratio between the lifetime achieved using our mechanism and that achieved in the original datasets. The resulting high gains arrive from the originally selected update intervals adopted in the datasets, which would lead sensors to last only a month (a time duration that coincides with the original time the sensors in the Intel lab were deployed). By adopting our approach, the same sensor deployment could last for five years, as the average update interval our DRL solution has determined is 49 minutes.

In Fig. 7 we compare the performance of our DDPG-based scheduling mechanism, in terms of achieved sensor lifetime, to three different methods of obtaining update times:

1) **Original**: as a baseline, we take the update times adopted in the Intel Lab and Smart Santander datasets. The baseline case reveals the original expected lifetime of deployments,
Fig. 7: Achieved expected lifetime in years with every approach for all five datasets. The number on top of each bar plot reveals how close each approach is to the Ideal case.

if the sensors were battery-powered. Note that for the SmartSantander datasets, we use the update time of the sensor that collected the most observations.

2) **DQN**: update times we obtain by using the Deep Q-Network approach we proposed in [1]. Note that the reward function we use for the DQN approach is the same as we defined in Eq. (15), while the action space consists of five actions. The scheduling mechanism can take an action to increase the sensor’s current update interval by one or ten time-steps, decrease it for one or ten time-steps, or keep it as it was.

3) **Ideal**: in the ideal case, the network controller acts essentially as an oracle that knows the ground truth and can obtain observations from any sensor on demand. With the ideal scheduler, sensors are asked to transmit only when the average error of estimated values (of temperature, humidity, ambient noise) exceeds the set threshold $\varepsilon^*$. In short, the ideal case represents the optimal solution possible in terms of the expected lifetime.

In Fig. 7, we show the expected lifetime we achieved using all four approaches for all five datasets. We calculated the lifetime using Eq. (6) and using values of average update times that we obtained with each approach. The results show that our mechanism is capable of finding update intervals that are very close to the ideal one. The only exception is for the case of Intel lab temperature data. In that case, a higher $U_{max}$ would enable the agent to get results
closer to the ideal case. However, by keeping the $U_{\text{max}}$ constant throughout our validation we can demonstrate the system’s robustness to multiple different scenarios. Similarly, for the DQN solution, we would have to increase the number of actions to be able to improve the overall performance. However, with a higher number of actions, the required training time increases drastically, which limits the DQN solution’s applicability to the proposed problem. Table III shows that the DDPG approach achieves $91 - 92\%$ of the error threshold, for every dataset, while the DQN approach varies slightly more due to the mechanism’s inability to adapt to the environmental changes promptly.

The importance of faster adaptability to an ever-changing environment is paramount in real deployments. In this criterion, the DDPG solution greatly outperforms the DQN approach even if results in Fig. 7 indicate very similar performance in terms of achieved lifetime. Additionally, we noticed that the DQN approach requires a longer exploration time, e.g., for the Intel dataset, we iterated over the exploration part of the data three times, in comparison to two iterations required to train the system using DDPG.

To improve the performance of the proposed DDPG approach in comparison to the ideal, the apparent solution is to provide the agent with more information, i.e., expand the ANN input state space. For example, adding information regarding the average distance to neighbouring sensors would help. However, adding the average distance as part of the state information would decrease the generality of our solution. Intuitively, providing the agent with direct information regarding all sensors in the system (current update interval, average estimation error, and energy level) should lead to better results. Unfortunately, a significantly larger state space would lead to longer computational time and even possibly a degradation in performance, as an agent could have a hard time differentiating between the more and the less relevant information, e.g., which sensor’s updates are most relevant for the current decision.

TABLE III: Obtained $\varepsilon$ per dataset.
The minimum and maximum expected lifetimes among all sensors are shown as a solid line in the middle of each bar in Fig. 7. The variation is especially noticeable in the case of Intel-Lab data, indicating that some sensors benefit more from using correlated information than others. For this dataset, sensors are deployed on the same floor, and those in the middle of the room are able to benefit more from correlated measurements collected from other nearby sensors.

We remind the reader that distances are not part of the information explicitly furnished to the learning agent. As we show in Fig. 8, in which we plot the achieved average update interval as a function of the average distance to other sensors, some sensors benefit more than others from information collected by their neighbors. Note that in our system each sensor represents the location at which we observe the physical phenomenon. More specifically, it appears that the average distance to other sensors is inversely proportional to the achieved update interval. We obtained the result using temperature test data for the Intel-lab dataset. The line in Fig. 8 is obtained using linear regression. Such behaviour is interesting as the agent does not have direct information regarding the distances, yet it can infer it from other available information. However, these differences appear only in the short term, as the energy-awareness ability of our proposed scheduling mechanism will in the longer run prevent one sensor from updating much more often than others and avoid the depletion of one sensor’s battery much earlier than the others.
B. Energy-aware Scheduling

In this subsection, we demonstrate the energy-aware capabilities of the proposed mechanism. We evaluate the energy-aware performance using Intel-laboratory temperature data, and in all experiments the scheduling mechanism controls 50 sensors.

First, we show the changes in the update interval and $\varepsilon_n$ over a number of episodes for two sensors. In Fig. 9(a) we plot the update interval over a number of episodes for a sensor with above-average available energy (75% of remaining battery life), while in Fig. 9(b) we plot update intervals of sensors with below-average energy (25% of battery life). Note that we set the energy levels for all other sensors to 50%, and that the two sensors were randomly selected. As we show, our updating mechanism sets the update interval of a sensor with less remaining energy significantly higher in comparison to the update interval of a sensor with more energy available. By setting different update intervals, the mechanism can, in the longer run, balance the energy levels among sensors. In other words, the mechanism forces the sensor with more energy to update more often than it would otherwise need to, in order to help preserve the energy of the sensor with shorter battery life. As we show in Fig. 9 (c) and (d), the set error threshold is not exceeded.

Fig. 10 shows the ratios of update rates of sensors with different energy levels. We set the energy level of 90 percent of sensors (45 out of 50) in the dataset to a fixed value. Then we change the energy level of the remaining ten percent of $\varepsilon$ sensors (5) in steps from 1% to 100% of remaining battery life. In each step we iterate over the test data and report the ratio between
the achieved average update rate of the two groups, i.e., $\frac{\lambda_{10\%}}{\lambda_{90\%}}$. As expected, when sensors have the same energy level, they will transmit with roughly the same update rate. We can observe an intriguing behaviour when sensors are close to depleting their energy. When a few sensors have much more energy than others, they will transmit new observations much more often, even 25 times more often when they have a full battery and the other sensors’ energy level is at 25%. By doing so, the mechanism effectively decides to use the energy of a few sensors to prolong the lifetime of all others. Over time, the tendency will be towards achieving more uniform energy use throughout the network.

VII. CONCLUSION

In this paper, we have proposed a DRL-based energy-aware scheduling mechanism capable of significantly prolonging the lifetime of a network of battery-powered sensors without hindering the overall performance of the sensing process. We have demonstrated, using real-world observations, that the performance of our proposed mechanism is near-optimal. Additionally, the proposed mechanism is capable of setting update intervals depending on the energy available.
on devices. Such behavior ensures that battery-powered sensors deployed at the same time will also expire at the same time, thus enabling infrastructure providers to replace the entire sensor deployment simultaneously. As such, the energy-aware scheduling mechanism we proposed in this paper can have a profound impact on the suitability of the future deployments of IoT sensing devices.

In our future work, we will focus on a network of sensors using diverse primary power sources, e.g., mains powered or event-based energy harvesting. In such a case, the resulting scheduling policy will depend on the type of power source the low-power sensor relies on.
