**Abstract.** In this paper we describe our intended approach for the verification of software written in imperative programming languages. We base our approach on model checking of graph transition systems, where each state is a graph and the transitions are specified by graph transformation rules. We believe that graph transformation is a very suitable technique to model the execution semantics of languages with dynamic memory allocation. Furthermore, such representation allows us to investigate the use of graph abstractions, which can mitigate the combinatorial explosion inherent to model checking. In addition to presenting our planned approach, we reason about its feasibility, and, by providing a brief comparison to other existing methods, we highlight the benefits and drawbacks that are expected.

## 1 Introduction

The verification of software systems has already been a venerable concern for some computer scientists. However, given the ever-growing use of software in our society, and the consequent problems and damages due to programming errors, over the last years this concern became more wide-spread and hence, attracted more attention from researchers. As a natural consequence of this fact, several different methods and techniques have been proposed and are being studied. One recent key change in such verification techniques is the development of approaches that can analyse the correctness of software written in commonly used imperative programming languages. Previously, those methods were limited to the so-called "modeling languages", which have a clean and simple definition and are thus more amenable to formal treatment. We can roughly divide current software verification techniques in two types: *deductive* or *exploratory*.

Deductive methods are mostly based on the principles defined by Floyd [19] and Hoare [22], and later refined by Dijkstra [13]. These methods rely on an axiomatic definition of the semantics of the programming language elements and on inference rules that allow one to reason about the desired correctness properties of a program in a compositional way. Among the tools developed under

* The work reported herein is being carried out as part of the GRAIL project, funded by NWO (Grant 612.000.632).

this approach we can cite the KeY System [6], Why/Krakatoa [18] and jStar [14] for the verification of Java programs, and the Spec# tool [4] for analysing code written in a super-set of the C# language.

Exploratory methods try to exhaustively (or partially) enumerate the possible states of a program. A program state corresponds to a snapshot of the program dynamic structures in memory, e.g., heap, stack, threads locks and program counters, etc. The transitions between states are given by the execution semantics of the language on which the program is written. In fact, an exhaustive exploration mechanism can be seen as a non-deterministic machine that generates all possible execution paths of the input program and produces a transition system, representing the program state space. A well known exploratory technique is model checking [3], where the desired correctness properties of the program are checked to hold over a finite transition system. Among currently available software model checkers we can cite Java PathFinder (JPF) [38] and Bogor [16] for Java, and MoonWalker [12] for C# programs.

The purpose of this paper is to present an overview of a new exploratory approach that we plan to develop for the verification of software. This approach is based on model checking of graph transition systems (GTS), where each program state is modeled as a graph and the exploration (execution) engine is specified by graph transformation rules. We believe that graph transformation [32] is a very suitable technique to model the execution semantics of languages with dynamic memory allocation. Furthermore, such representation provides a clean setting to investigate the use of graph abstractions, which can mitigate the space state explosion problem that is inherent to model checking techniques.

The rest of this paper is organized as follows. In Sect. 2 we explain the underlying concepts of our approach, viz., graph transformations and graph abstractions. The planned verification approach is given in Sect. 3, and a discussion about its feasibility is presented in Sect. 4. Related work is given in Sect. 5, and Sect. 6 concludes the paper.

## 2 Concepts

In this section we present the two techniques on which we base our verification approach: graph transformation and graph abstraction. These techniques are very generic and can be used in various settings, thus we focus our presentation of the concepts to the relevant aspects of our problem at hand.

### 2.1 Graph Transformations

Graph transformation (or graph rewriting) is a rule-based transformation technique with a solid theoretical foundation [32]. We use the term *graph production system* (GPS) to refer to a set of graph transformation rules. Each rule specifies both the conditions under which it can be applied and the changes to be performed. A transformation rule is composed of two graphs, a left hand side (LHS) and a right hand side (RHS), and is applied to a host graph, i.e., the graph to

```
public class Cell {
  public Object val;
  public Cell next;
}

public class Buffer {
  private Cell first, last;

  public Buffer() {
    first = new Cell();
    first.next = new Cell();
    first.next.next = new Cell();
    last = first.next.next;
    last.next = first;
  }

  public void put(Object arg) {
    if (last.next.val == null) {
      last = last.next;
      last.val = arg;
    }
  }

  public void drop() {
    if (first.val != null) {
      first.val = null;
      first = first.next;
    }
  }
}
```

**Fig. 1.** A Java example of a circular buffer with three cells.

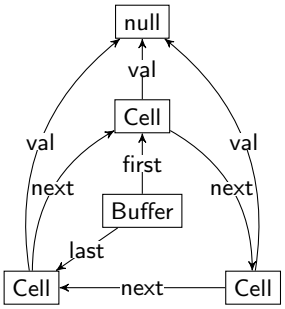
be transformed. In general terms, a rule is applied by searching for an image of the LHS on the host graph and by replacing the found image with a copy of the RHS. This search for a LHS image corresponds to the subgraph matching problem (see Sect. 4).

A GPS can be used to simulate the execution semantics of a programming language. We illustrate this with a simple example. Consider the snippet of Java code shown in Fig. 1, which implements a circular buffer with three `Cell`s. Each `Cell` has two fields: `next`, a reference to its adjacent position, and `val`, which can hold a reference to an `Object`. The state of a `Buffer` object in memory, immediately after the execution of its constructor, can be easily captured by a graph, depicted in Fig. 2(a). In this representation, nodes stand for instances of classes, or primitive values, and edges represent the references (object fields). The `Buffer` class has two methods, `put` and `drop`.

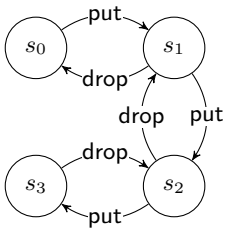
Method `put` inserts the given argument `Object` after the current `last` element, provided that the `Buffer` is not full. Figure 2(c) shows the graph transformation rule that models the execution of the `put` method. The LHS defines the nodes and edges of the host graph involved in the transformation and provides the conditions for the rule application, i.e., `last.next.val == null`. The argument of the `put` method is assumed to have an arbitrary non-null value $x$. The RHS of the `put` rule establishes the effect of the rule application, i.e., the `next` pointer is moved and the argument value is stored.

Method `drop` discards the `first` element of a non-empty `Buffer`. The corresponding transformation rule is given in Fig. 2(d). The node label $\{?x[!\texttt{null}]\}$ in the LHS can be seen as a regular expression that matches with any node in the host graph except the `null` node.

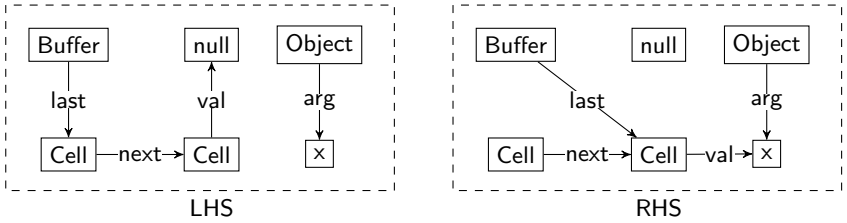
The exploration of all possible applications of the `put` and `drop` rules over the initial host graph shown in Fig. 2(a) yields a graph transition system (GTS) that captures all possible states of a `Buffer` object. If we consider that the arbitrary value $x$ of the argument of `put` is drawn from a finite set $D$ with cardinality $\#D = k$, the number $n$ of states of the GTS in this example can be determined *a priory*, and is given by the formula $n = \frac{k^4-1}{k-1}$, for $k > 1$. Assuming that $D$



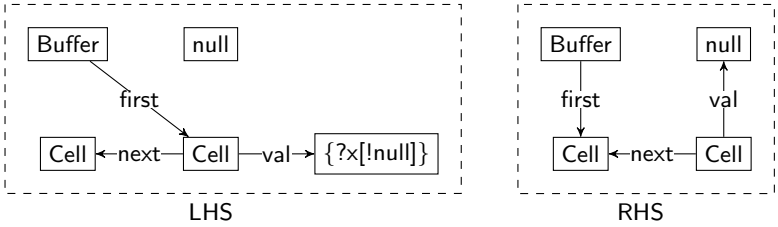
(a) Graph representation of `Buffer` state after the constructor call.



(b) Transition system of the `Buffer` GPS, after data abstraction.



(c) `put` transformation rule.



(d) `drop` transformation rule

**Fig. 2.** (a), (c), and (d): Graph production system that captures the execution semantics of the Java program given in Fig. 1. (b): A graph transition system, see Sect. 2.2.

represents the set of Java integers, we have that $k = 2^{32}$, and thus the value of $n$, even for such a small example, is already flabbergasting. In order to control such blow-up we need to abstract away irrelevant information.

### 2.2 Abstract Interpretation

Continuing with the discussion of the previous section, the kind of information that can be considered irrelevant is dependent on the properties that one wishes to verify. For the circular buffer example, we might want to check if indeed no element is inserted if the buffer is full. In the GTS, this property $p$ means that no

execution path with more than three applications of the `put` rule exists. To verify such property, it is not necessary to keep track of the concrete values stored in the buffer; it suffices to know that the values are `non-null`. This simplifies the GTS to only 4 states, shown in Fig. 2(b), and makes the verification of $p$ a trivial task.

The abstraction just described can be placed within the theory of abstract interpretation, developed by Cousot and Cousot [10]. An abstraction from a subset of concrete values from set $C$ to an element of an abstract set $A$ is given by an *abstraction function* $\alpha : 2^C \to A$, and conversely by a *concretization function* $\gamma : A \to 2^C$. The elements of $C$ and $A$ are required to be ordered in a lattice and $\alpha$ and $\gamma$ must be monotonic with respect to this ordering. In our example, $C = D \cup \{\texttt{null}\}$, with an ordering ($\texttt{null} \sqsubseteq D$); and $A = \{\bot, \texttt{null}, \texttt{non-null}, \top\}$, with an ordering ($\bot \sqsubseteq \texttt{null} \sqsubseteq \texttt{non-null} \sqsubseteq \top$). The abstraction and concretization functions are defined as

$$\begin{aligned} \alpha(D \cup \{\texttt{null}\}) &= \top & \qquad \gamma(\top) &= D \cup \{\texttt{null}\} \\ \alpha(D) &= \texttt{non-null} & \gamma(\texttt{non-null}) &= D \\ \alpha(\{\texttt{null}\}) &= \texttt{null} & \gamma(\texttt{null}) &= \{\texttt{null}\} \\ \alpha(\varnothing) &= \bot & \gamma(\bot) &= \varnothing \quad . \end{aligned}$$

In this example $\gamma = \alpha^{-1}$, but this is not generally the case. The $\top$ value is the most relaxed abstraction and represents every subset of $C$. On the other hand, $\bot$ is the most coarse approximation and thus maps to the empty set.

The key point of an abstract interpretation is that, with respect to the correctness properties that one wants to verify, the abstraction is an over-approximation of the concrete system. Thus, if a property holds on the abstract domain, it is guaranteed to hold on the concrete domain. This is the reason why we can check the correctness of the program of Fig. 1 using the abstract GTS of Fig. 2(b). However, it might be the case, due to loss of precision in the abstraction, that a property does not hold on the abstract domain but actually holds in the concrete domain, a so-called *false positive* error report.

### 2.3 Graph Abstractions

The example of the previous section is an interesting case of abstraction from the data domain of the program, which can be used to shrink the program state space to a reasonable size. However, such abstraction fails to cope with structures of unbounded size, e.g., a linked list. Regardless of data abstraction, the transition system of a such structure is infinite and thus unsuitable to exploratory verification methods without some previous manipulation. What we need is a method to deal with the graph structure, i.e., we need to abstract a possible infinite state graph to a finite graph.

A graph abstraction is based on the concepts of shape analysis, proposed by Sagiv et al. [33, 34], and of abstract interpretation. A *graph shape* is an abstraction that captures the underlying structure of a set of concrete graphs, acting

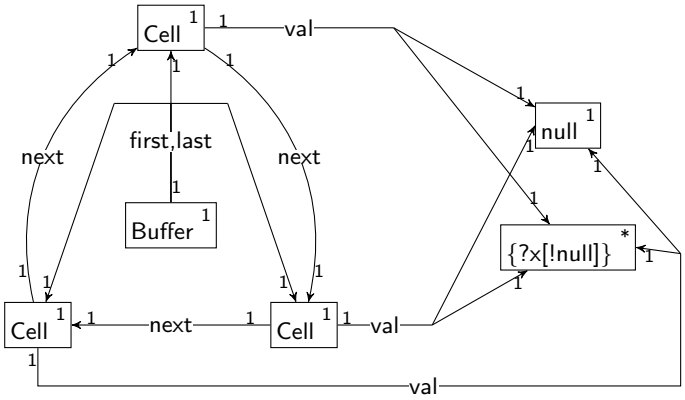


**Fig. 3.** Graph shape abstraction of the concrete states of the GTS in Fig. 2(b)

as their representative in the abstracted domain. The basis of this technique falls within the same idea of abstract interpretation presented in the previous section, except that now the abstraction function maps a set of concrete graphs to a corresponding graph shape. Returning once more to the circular buffer example, Fig. 3 shows a graph shape that captures all possible states of the buffer. Each node (resp. edge) of a graph shape is marked with a *multiplicity*, indicating how many nodes (resp. edges) must (or may) be present in a concrete graph. In Fig. 3 we see that only one occurrence of a `null` and `Buffer` node is allowed, as indicated by the multiplicity 1 in the upper right corner of the nodes of the graph shape. Similarly, we see three mandatory `Cell` nodes and zero or more `non-null` value nodes (marked with multiplicity *). The edges of a graph shape are in fact hyper-edges, with a set of source and target nodes. The concretization of an abstract hyper-edge amount to all possible combinations of source and target node sets. In Fig. 3, the hyper-edges labeled with `first` and `last` show that each of these fields in a concrete graph can point to any of the three cells of the buffer.

## 3 Approach

Now that we have presented the most important underlying concepts, let us discuss how they can be combined in our intended approach for software verification. Figure 4 provides a picture of the whole verification cycle. The input is the program source code, written in some programming language, e.g., Java. The code is analysed by a compiler that produces as output an abstract syntax graph (ASG). This ASG is essentially the usual abstract syntax tree produced by a language parser enriched with type and variable bindings. The ASG, together with definitions of the language control flow semantics, is the input of a flow construction mechanism, that builds a flow graph for the given ASG. This flow graph represents how the execution point of the program should flow through

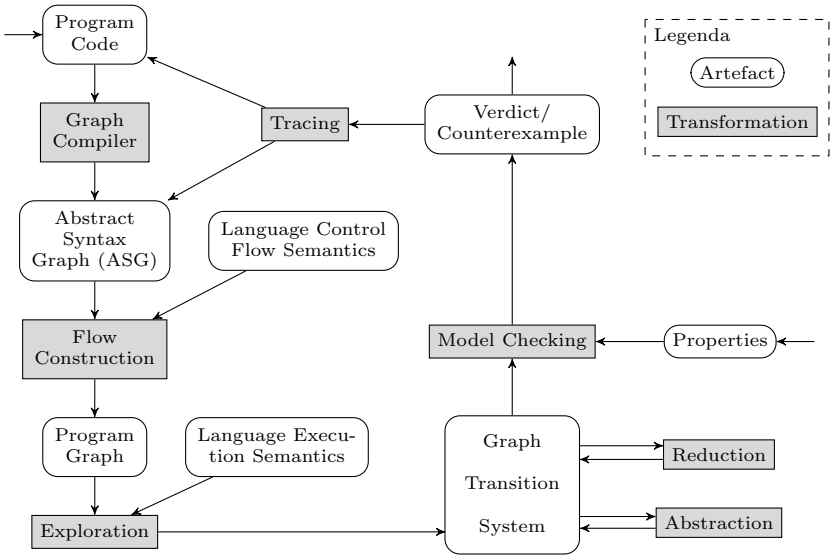

**Fig. 4.** Overview of the verification cycle proposed.

the ASG, according to the rules of the programming language in use. Together, an ASG and a flow graph form a program graph, an executable representation of the program code as a graph.

We can now feed the program graph to an exploratory graph transformation system, composed by graph transformation rules that capture the execution semantics of the elements of the programming language, to exhaustively explore the state space of the program graph. This exploration produces a graph transition system (GTS) that captures all possible paths of execution of the program. However, as discussed in Sect. 2, a program GTS may be finite but still prohibitively large, or even infinite. At this point the previously discussed abstraction techniques come into play, in order to produce a finite GTS. Additionally, we may profit from our representation of states as graphs and use a graph isomorphism algorithm to collapse isomorphic states into a single representative, thus reducing the size of the GTS. This is further discussed in Sect. 4.

After producing the GTS, we can perform model checking against a given set of correctness properties that the program is expected to have. This check produces either a verdict that the program is indeed correct, or a counter-example of an execution path that produces an error. This counter-example can then be traced back to the ASG, or, better yet, the input code, so that the user can inspect the error. As an exploration/model checking engine we will use GROOVE [26], a tool specifically developed to perform model checking of graph production systems.

## 4 Discussion

As noted by Dwyer et al. [17], the combination of model checking with abstraction techniques is an emerging trend. The new idea in our proposal is to use graphs and graph transformations as a base of state representation and state space exploration. Although, at first, this may seem to introduce a lot of unnecessary complexity into an already complex problem, after a careful analysis we can see that this is not the case.

**On the complexity of the subgraph matching problem.** The general case of the subgraph matching problem is known to be NP-complete [20]. However, there are several cases for which solving this problem is much easier. For example, in the case where the rules and the host graph contain a root label, Dodds and Plump [15] showed that the matching can be done in constant time. Even on the general case, heuristics can be used to improve the execution time of the matching algorithm. The work of Geiß et al. [21] shows how the search plan heuristic can be used for this purpose. Another interesting improvement is described in the work of Bergmann et al. [7], which presents a solution with incremental pattern matching, where sets of matchings of graph transformation rules are stored and incrementally updated as the host graph changes.

**Isomorphism for state space reduction.** As noted in Sect. 3, our choice of graphs to represent states allows us to perform symmetry reduction of the state space by using graph isomorphism algorithms. The graph isomorphism problem belongs to the NP complexity class but it is still not known whether the general case of the problem is either solvable in polynomial time or is NP-complete. However, in practice the problem can often be solved efficiently [25]. Furthermore, this is an optional optimization in our verification cycle that can be switched off if the cost of isomorphism checking is higher than the actual gain on the state space reduction (which is the case if the expected symmetry is low).

The collapsing of states under isomorphism particularly pays off when the states representation of a problem have a high degree of symmetry. An interesting study on one of such cases was conducted by Crouzen, Van de Pol, and Rensink [11]. In this study, the protocol of an ad-hoc self-configuring communication network was analysed with two model checking tools: GROOVE, based on graph transformations; and $\mu$CRL, based on process algebra. In that particular problem, the study showed that isomorphism symmetry checks can reduce the state space in several orders of magnitude. In [28], Rensink presents the current implementation of isomorphism checking in GROOVE, based on graph certificates.

**Drawbacks.** Every verification method has strengths and weaknesses, and ours is no different. A problem with usual model checking techniques is the need of a "whole-world" model of the system. In our case, no provision is currently available for compositional verification, for example, of language libraries. Therefore,

the implementation of the libraries elements that are used in the input program must also be given as input.

Another issue are abstractions that may produce a large number of false positives, and thus place a heavy burden on the user, i.e., to check if indeed all the reported problems correspond to real errors. Care must be taken during the design of abstractions so that the number of false positives reported is low.

**On capturing the program execution semantics as graph transformation rules.** In our running example of the circular buffer (Fig. 2) we presented graph transformation rules that simulate the execution of the whole bodies of methods `put` and `drop`. This was done to provide a clearer picture of the concepts that we use. However, it should be noted that it is not possible to provide an automatic way to translate a whole method body to a single rule, simply because the number of methods that a programmer can create is infinite. Therefore, we work on a more fine-grained level: we provide transformation rules based on the execution semantics of the elements of the language, e.g., assignments, object creation, method invocation, etc. This once more stress the analogy of a GTS exploration mechanism and a virtual machine.

## 5 Related Work

The amount of research dedicated to software verification is enormous. Here we limit ourselves to the investigations that we consider most similar to our proposed approach.

The use of graph isomorphism for state symmetry reduction was investigated by Turner et al. [37], and Spermann and Leuschel [36], in the context of the ProB model checker. In their work, the internal model checker representation of a state was translated to a graph, that was then given to an external isomorphism checking tool: Nauty [25]. They report empirical results to show the effectiveness on the state space reduction. A large part of their work was devoted to the translation to a graph representation, a problem that we do not face. Other researchers address the problem of symmetry reduction directly over the internal state representation of their model checker of choice. This is the case of Lerda and Visser [24] for Java PathFinder, and Robby et al. [31] for Bogor.

The automatic extraction of a finite-state model from Java code for the purpose of model checking was addressed by Corbett et al. [8], with the Bandera tool set. They also propose the use of data abstraction as one of the techniques for building tractable models for verification. Our approach could also benefit from their Slicer component, that remove variables and structures from the code that are not relevant for checking a certain property.

Anand, Păsăreanu and Visser [1] proposed the use of abstraction and shape analysis in the context of symbolic model checking. Again, a program state (captured by a symbolic heap configuration) was represented using a graph-based formalism. Their method for symbolic states subsumption and matching is quite similar to our proposal to use graph abstraction and graph shapes. A

drawback of their approach is the need for code instrumentation, which in our case we believe will not be required. An interesting aspect of the work by these authors is that the use of symbolic execution allows for modular verification of compilation units, e.g., libraries. They implemented symbolic execution as an extension of JPF [2].

## 6 Conclusion

In this paper we present a new approach for software verification that combines the techniques of graph transformation, model checking, and abstract interpretation. Other approaches that combine model checking and abstraction eventually are forced to provide a translation from an internal state representation to a graph-based one. We believe that this translation is often cumbersome and unattractive. The novelty in our method is to use an explicit representation of program states as graphs, and to rely on graph transformations as a computational engine. In doing so, we lift ourselves from the intricacies of a specific model checker implementation and we arrive at a very clean setting to study abstractions over program states.

The development of our approach is at an early stage. We chose Java as an initial programming language to handle, due to its wide-spread use. So far we have a graph compiler that produces an abstract syntax graph from any legal Java program. The details of the construction of this compiler are presented in [30]. At the moment of this writing we are working on the formalism of the control flow semantics of Java for the flow construction mechanism. The next step will be the elaboration of the execution semantics of Java in terms of graph transformation rules. When arriving at this point we will be able to use the GROOVE tool [26] as an exploration/model checking engine. The most challenging part is then to elaborate good graph abstractions that keep the state space explosion under control while still allowing the verification of interesting properties on realistic programs.

It should be noted all the ingredients of our proposed approach were previously investigated and their feasibility analysed. How graph transformations can be used to capture the execution semantics of a programming language was shown in [23]. The construction of a control flow semantics specification for a large part of Java was given in [35]. Initial studies on graph abstraction techniques were proposed in [27], [29] and [5]. Nevertheless, whether the combination of these techniques will indeed provide good practical results when applied to reasonable sized programs is still to be seen.
