Density functional theory is used to explore the possibility of inducing impurity band ferromagnetism in monolayers of semiconducting MoS\(_2\) by introducing holes into the narrow Mo 4\(d\) band that forms the top of the valence band. A large out-of-plane anisotropy is found for unpaired spins bound to the substitutional acceptor impurities V, Nb, and Ta that couple ferromagnetically for all but the shortest separations. Using the separation-dependent exchange interactions as the input to Monte Carlo calculations, we estimate ordering temperatures as a function of the impurity concentration. For about 9% of V impurities, Curie temperatures in excess of 160 K are predicted. The singlet formation at short separations that limits the ordering temperature is explained and we suggest how it can be circumvented.

Introduction. The extraordinary interest sparked by the discovery of intrinsic ferromagnetism in the two-dimensional van der Waals semiconducting crystals CrGeTe\(_3\) [1] and CrI\(_3\) [2] has led us to examine the possibility of inducing ferromagnetism in monolayers of MoS\(_2\) by doping the narrow Mo \(d\) band that forms the top of the valence band with holes. Theoretical analyses of the MX\(_2\) layered transition-metal dichalcogenides (\(M = \text{Mo, W}; X = \text{S, Se, Te}\)) more than 40 years ago [3,4] revealed the curious electronic structure shown in Fig. 1. The \(d\) valence states of the Mo atoms interact with the chalcogen \(p\) states to form a substantial band gap, leaving a single “nonbonding” Mo \(d\) band (left-hand side, solid red line) in the hybridization gap between bonding states (dashed black lines, with nominal \(Xp\) character) and antibonding states (dashed red lines, with nominal Mo \(d\) character). The projected densities of states (DOS) in Fig. 1(b) show the considerable mixing that actually occurs. The reduced coordination number of metal atoms in two-dimensional structures leads to smaller bandwidths and higher state densities than in three dimensions, making this system favorable for the occurrence of itinerant ferromagnetism. Motivated by predictions of high-temperature ferromagnetism in narrow impurity bands [5], we examine the behavior of single acceptor states in the low concentration regime. We show that Mo\(_{1-x}\)V\(_x\)S\(_2\) monolayers should become ferromagnetic semiconductors with Curie temperatures much larger than those found for either CrGeTe\(_3\) or CrI\(_3\).

Monolayers of MoS\(_2\) were among the first two-dimensional (2D) materials to be prepared by micromechanical exfoliation [6]. Renewed interest in this otherwise well-known semiconductor was rekindled by the subsequent observation that the monolayer band gaps were direct [7] and substantially larger than for the bulk [8], and by the realization of transistors with large on/off ratios [9]. A direct band gap makes MX\(_2\) semiconductors promising candidates for optoelectronic applications. The lack of inversion symmetry in monolayer transition-metal dichalcogenides (TMDs) and large spin-orbit splitting of the degenerate \(K\) and \(K’\) valence band maxima is promising for the subject of “valleytronics” whereby carriers in different valleys can be manipulated using magnetic fields, magnetic substrates, and optical pumping [10–12]. The exchange interaction introduced by a magnetic

![FIG. 1. (a) The band structure of an MoS\(_2\) monolayer and (b) the corresponding total, and Mo-\(d\) and S-\(p\) projected densities of states. dopant can break the time-reversal symmetry and lead to valley polarization [13]. According to the Mermin-Wagner theorem [14], there is no long-range ferromagnetic ordering in a strictly two-dimensional (2D) isotropic Heisenberg model. However, the theorem is invalidated by magnetic anisotropy and many observations of magnetic ordering in thin layers of metallic ferromagnets as well as recent discoveries [1,2] show that this frequently happens in practice.

Doping $M_X$ monolayers has been considered theoretically with various defects and substitutions leading to the formation of local moments [15–30]. However, no attempt has been made to calculate magnetic anisotropies without which there is no long-range ferromagnetism and only a few attempts have been made to study the separation dependence of the exchange interaction [18,19,30]. The coupling between impurities is determined by the range of the localized impurity states; the deeper the levels are, the shorter the range of the effective interaction and the lower the ordering temperature for a given concentration of dopant. The short range of the effective exchange interaction leads to percolation and requires such heavy doping to achieve coherent magnetic ordering [31] that the final material is no longer a semiconductor. Motivated by the electronic structure shown in Fig. 1 and the promise of high-temperature ferromagnetism in narrow impurity bands [5], we adopt a different approach to making a magnetic semiconductor out of MoS$_2$. By introducing a low concentration of holes into the top of the narrow valence band, we explore the possibility of realizing a material that is ferromagnetic while remaining a semiconductor.

**Method.** Total energy calculations and structural optimizations were carried out within the framework of density functional theory (DFT) using the projector augmented-wave (PAW) method [32] and a plane-wave basis with a cutoff energy of 400 eV as implemented in the VASP code [33–35]. We use the local spin density approximation (LSDA) as parametrized by Perdew and Zunger [36] to describe exchange and correlation effects because it accurately reproduces the experimentally observed ordering of the valence band maxima [37]. Monolayers of MoS$_2$ periodically repeated in the $c$ direction were separated by more than 20 Å of vacuum to minimize the interaction. Substitutional impurities and impurity pairs were modeled using $N \times N$ in-plane supercells with $N$ as large as 15; interactions between pairs of impurities were studied in 12 × 12 supercells to reduce interactions between periodic images to an acceptable level. Atomic positions were relaxed using a $2 \times 2 \times 1$ Γ-centered $k$-point mesh until the forces on each ion were smaller than 0.01 eV/Å. Spin-polarized calculations were performed with a denser mesh corresponding to $4 \times 4 \times 4$ $k$ points for a $12 \times 12$ unit cell.

**Single impurity limit.** We begin by substituting a single Mo atom in a 12 × 12 MoS$_2$ supercell with 3$d$, 4$d$, or 5$d$ atoms that have one or two valence electrons more or less than Mo. The energy of this 432-atom supercell is first minimized with respect to the atomic coordinates. The resulting energy levels found in the gap without spin polarization for the 12 dopant atoms considered are summarized in Fig. 1. All 3$d$, 4$d$, and 5$d$ ions with one or two electrons fewer than Mo introduce shallow acceptor states as measured by the proximity of the lowest unoccupied or partially occupied electron level to the top of the valence band. Re and Tc form shallow donors but the other four elements Mn, Fe, Ru, and Os give rise to deep levels and will not be considered further here. The magnetic moments obtained when spin polarization is included are given in Table I. The single shallow acceptors V, Nb, and Ta and donors Tc and Re are found to polarize completely while the double acceptors and double donors (but not Fe) are spin compensated.

The formation energy [38] of MoS$_2$:V is a modest 0.4 eV, while those of Nb and Ta are 0.01 and −0.12 eV, respectively, indicating that it should not be very difficult to substitutionally dope MoS$_2$ with these 4+ ions [27,39,40] that have a $d^1$ configuration, a single unpaired spin. Under the local $D_{3h}$ symmetry of a Mo atom, the Coulomb potential of a substitutional single acceptor leads to the formation of a doubly degenerate $e'$ state with $d_{x^2−y^2}$ and $d_{3z^2−r^2}$ character bound to the $K$ and $K'$ valence band maxima (VBM) with a Bohr radius of ~8 Å as well as an $a'_1$ state bound to the slightly lower lying Γ-point VBM with $d_{3z^2−r^2}$ character and a Bohr radius of ~4 Å. In supercell calculations for single V substitutional impurities, these three levels form partially filled overlapping states. The results for the magnetic moments shown in Table II can be understood in terms of (i) these supercell-size dependent results and (ii) use of the generalized gradient approximation (GGA) that results in the Γ-point VBM being too high [37] and the hole occupying the $a'_1$ bound state [16,17,21–23,26–28,30].

**Exchange interaction.** We estimate the exchange interaction between pairs of V, Nb, and Ta dopant atoms by calculating the total energies for substitutional pairs as a function of their separation with their magnetic moments aligned parallel (“ferromagnetically,” FM) and antiparallel

ITINERANT FERROMAGNETISM IN p-DOPED ... PHYSICAL REVIEW B 99, 220406(R) (2019)

FIG. 2. The difference between the total energies of antiferromagnetic and ferromagnetic states (black) and the pair binding energy (red) for pairs of V substitutional impurities plotted as a function of their separation for unrelaxed (open symbols) and fully relaxed (solid symbols) configurations in 12 \times 12 MoS_2 supercells. The dashed black curve extrapolates the relaxed results to separations where quenching occurs.

(“antiferromagnetically.” AFM) in 12 \times 12 supercells, with and without atomic relaxation. With one dopant atom at the origin, we explore all inequivalent sites in the 12 \times 12 supercell with the second dopant atom. The binding energy of V pairs is the energy difference \( E_b(R) = E(R) - E(R = \infty) \), where \( E(R) \) is the local density approximation (LDA) total energy for a supercell with two dopants separated by a distance \( R \). \( E_b \) is shown as a function of \( R \) in Fig. 2 (left-hand side), along with the energy difference between antiferromagnetic and ferromagnetic states (right-hand side axis). It has a maximum magnitude of \( \sim 0.3 \) eV for V dopants on nearest-neighbor lattice sites and decays essentially monotonically as a function of the separation. Because it is so small, it can be assumed that dopant atoms will be randomly distributed in real materials that are not fully equilibrated.

Two unpaired spins usually form a singlet state to maximize their bonding energy. We find that unrelaxed pairs of dopant atoms couple ferromagnetically for all separations. V pairs are more strongly coupled than Nb pairs that are more strongly coupled than Ta pairs. When relaxation is included, the magnetic moment is quenched for atoms closer than a critical separation, and in the case of V this is \( \sim 9.4 \) Å (see Fig. 2). As expected for hydrogenic defect states that are more localized by a stronger central cell potential, the exchange interaction decays faster with increasing separation for V than for Nb than for Ta. To a good approximation the exchange interaction decays exponentially with increasing separation with decay lengths of \( 3.6, 5.2, \) and 5.8 Å, respectively.

According to the Mermin-Wagner theorem [14], isotropic Heisenberg exchange will not yield a finite ordering temperature in two dimensions. However, \( MX_2 \) monolayers do not have inversion symmetry and spin-orbit coupling (SOC) leads to a substantial splitting of the Kramers degenerate states at \( K \) and \( K' \) with \( d_{xy}/d_{x^2−y^2} \) character [41]. In the single impurity limit, we find a 132-meV SOC-induced splitting of the \( ε' \) level that results in a large single ion magnetic anisotropy (SIA) of about 5 meV with preferred orientation of the magnetic moment perpendicular to the monolayer plane. The SIA is much larger than the value reported for 2D CrI\(_3\) that exhibits Ising behavior [42].

Curie temperature. In the case of very strong SIA, the system can be described by an Ising model yielding a magnetically ordered phase at finite temperature [43,44]. We treat the V (Nb and Ta) doped MoS\(_2\) monolayer as an Ising spin system and combine the exchange interactions calculated above with Monte Carlo calculations to estimate ferromagnetic Curie temperatures \( T_C \) with Binder’s cumulant method [45,46]. The fourth-order cumulant of the magnetization \( m \), \( \langle m(T) \rangle = 1 − ⟨ m^4 ⟩/3⟨ m^2 ⟩^2 \), is calculated for three different lattice sizes \( L = 50, 75, 100 \) as a function of the temperature \( T \) and the ordering temperature is given by the size-independent universal fixed point where the \( U_L(T) \) curves intersect for different lattices sizes \( L \); see the inset of Fig. 3.

The resulting values of \( T_c(x) \) are shown in Fig. 3 for V doping concentrations \( x \) in the range from 1% to 11%. \( T_C \) initially increases with increasing doping, and reaches a maximum value of \( \sim 165 \) K (Nb and Ta are lower) for a concentration of \( \sim 9\% \) before decreasing again for larger values of \( x \) (squares, solid line). For the exchange interaction calculated without relaxation, there is no maximum and \( T_C \) increases monotonically with concentration (circles, solid line). If we extrapolate the relaxed exchange interaction to close separations where quenching occurs (dashed line in Fig. 2), we find the ordering temperatures shown as a dashed line in Fig. 3. The behavior at close separations is limiting the maximum Curie temperature attainable, making it important to understand the nature of the quenching. We examine this for the case of V.
The doubly degenerate (green bands). Without relaxation, the $\pi$ bond (left-hand side) and this leads to holes occupying antibonding states [Fig. 4(a) inset]. The exponential decrease of $\Delta_\pi$ for one hole on each bond is weaker than $\Delta_1$ for a single V impurity that would imply partial quenching of the magnetic moments. For the ordered V dopants studied in Table II, this quenching occurs as the concentration is increased above 3% and is complete by 6%. In this context, we note that our LDA results provide a lower bound on the exchange interaction and ordering temperature which would be enhanced with a small Coulomb $U$ in LDA+$U$ calculations; a value of $U = 1$ eV is sufficient to make a $3 \times 3$ system ferromagnetic.

**Conclusions.** Although the maximum value of $T_C$ we find is below room temperature, the $MX_2$ material system offers many possibilities to tune both host and dopant (electrons as well as holes) properties. The observation of strong room-temperature ferromagnetism in VSe$_2$ [50] confirms that the $MX_2$ system may host interesting new magnetic effects. Very recently, there have been intriguing reports of room-temperature ferromagnetism in monolayers of WSe$_2$ [51] and MoTe$_2$ [52] lightly doped with vanadium.

**Quenching of moments for close dopant pairs.** The magnetic moments of V dopant atoms couple ferromagnetically at separations larger than 9.4 Å and are quenched at closer separations (Fig. 2). In the absence of relaxation, however, we find that V atoms couple ferromagnetically for all separations. To understand the role of the local atomic relaxation in quenching the FM coupling, we consider a $12 \times 12$ supercell of MoS$_2$ doped with a pair of V atoms on neighboring Mo sites. The spin-unpolarized supercell band structures and DOS with (right) and without (left) relaxation are shown in Fig. 4. $a'_1$ states with $d_{3z^2-r^2}$ orbital character on the neighboring V atoms form a $\pi$ bond (red bands) while the orbitally degenerate $e'$ states with $d_{xy}/d_{x^2-y^2}$ character form $\sigma$ bonds (green bands). Without relaxation, the $\pi$ bond is weaker than the $\sigma$ bond (left-hand side) and this leads to holes occupying the doubly degenerate $e'$ antibonding states [Fig. 4(a) inset]. In the periodic supercell, this leads to a peak in the DOS at the Fermi level and a magnetic instability.

Relaxation results in a structure where the S atoms move closer to the V atoms and the two V atoms move slightly apart. The reduced V-S bond length strengthens the $\pi$ bond by the increased hybridization between V $d_{3z^2-r^2}$ and S $p$ orbitals. The $\sigma$ bonds formed by the V $d_{xy}$, $d_{x^2-y^2}$ orbitals are weakened by the increased V-V separation; compare the $a - a^*$ ($\Delta_\sigma$) and $e - e'$ splittings in Figs. 4(a) and 4(b). Now all states are fully filled or empty, both holes occupy the $a^*$ antibonding singlet spin state, and there is no magnetic instability. This situation is energetically favorable as long as the energy gain from bonding ($\Delta_\pi$ for one hole on each dopant) is larger than the energy gain from exchange splitting. The exponential decrease of $\Delta_\pi$ with increasing dopant separation and almost constant exchange splitting [47–49] results in quenching of the magnetic moment at close separations while a triplet state forms when the bonding interaction becomes weaker than the exchange splitting at larger separations.

**Discussion.** The quenching of ferromagnetic pairing for close impurity pairs can be avoided by considering the host semiconductors MoSe$_2$ or MoTe$_2$ (WSe$_2$ or WTe$_2$) for which the $\Gamma$ point VBM drops with respect to the $K$-$K'$ VBM as $S \rightarrow Se \rightarrow Te$. Preliminary calculations show that the $a'_1$ defect levels follow the $\Gamma$ point VBM, leaving the holes in the orbitally degenerate $e'$ derived impurity bands. Double acceptors would be expected to have larger magnetic moments and exchange splittings (but also be more localized and more susceptible to Jahn-Teller distortions). The $MX_2$ system offers many possibilities to tune the magnetic properties of electron- and hole-doped monolayers by varying the composition of the host system with $M = Cr$, Mo, W and $X = S$, Se, Te or alloys of these constituents on either the $M$ or $X$ sublattice.

As the impurity concentration is increased, the impurity levels will overlap to form narrow bands that broaden and eventually overlap the narrow Mo band that forms the top of the valence band. For itinerant electrons occupying narrow bands, it has been argued that the effective interaction predicted by the Stoner criterion will not be reduced by correlation effects or spin-wave excitations [5]. For the 9% V dopant concentration for which $T_C$ is maximum, we find an $e'$ impurity bandwidth of $\sim 400$ meV. The $a'_1$ band is even narrower, only about a third as wide. Both exceed the 90-meV exchange splitting we find for single V impurities that would imply partial quenching of the magnetic moments. For the ordered V dopants studied in Table II, this quenching occurs as the concentration is increased above 3% and is complete by 6%. In this context, we note that our LDA results provide a lower bound on the exchange interaction and ordering temperature which would be enhanced with a small Coulomb $U$ in LDA+$U$ calculations; a value of $U = 1$ eV is sufficient to make a $3 \times 3$ system ferromagnetic.

**FIG. 4.** Unpolarized electronic structure for a $12 \times 12$ MoS$_2$ supercell with two V atoms on nearest-neighbor Mo sites. Band structure and DOS for the system (a) without and (b) with atomic relaxation. Defect bands are highlighted in red and green. The insets show the coupling scheme of two adjacent VS$_6$ units with unrelaxed (left) and relaxed atomic positions (right).

[38] The formation energy of a substitutional dopant is defined as $E_{\text{form}}[\text{MoS}_2 : X] = E_{\text{tot}}[\text{MoS}_2 : X] - E_{\text{tot}}[\text{MoS}_2] + \mu_{\text{Mo}} - \mu_{X}$, where $E_{\text{tot}}[\text{MoS}_2 : X]$ is the total energy of a supercell of monolayer MoS2 with one Mo atom substitutionally replaced by one dopant X atom, $E_{\text{tot}}[\text{MoS}_2]$ is the total energy of the same supercell of pristine monolayer MoS2, and $\mu_{\text{Mo}}$ and $\mu_{X}$ are the chemical potentials of Mo and X in the bulk bcc phase, respectively.
