RESULTS & DISCUSSION: All the smart-ELRs were subjected to (de-)phosphorylation reactions. In all cases, the Mass spectrometry showed a difference in molecular weight of 796 Da that corresponds exactly to 10 phosphate groups. The turbidity analysis revealed an evident shift in Tt (around 12 °C) between the phosphorylated and the de-phosphorylated ELRs. The Mass spectrometry and the turbidity analysis revealed a completely reversibility of the reaction. At mild conditions the de-phosphorylated ELRs formed aggregates, contrary to the phosphorylated ones. The RNAse activity assay revealed a modular RNAse catalytic activity depending from the smart-ELRs state.

CONCLUSIONS: A new smart-ELR having a dual enzyme-responsiveness was developed. The selective (de-)phosphorylation response of the serine residues modulate the smart-ELR state, with a consequent change for the RNAse catalytic activity.

INTRODUCTION: Bioprinting using micro-stereolithography offers advantages in printing resolution and viability rate of the encapsulated cells. In this work we demonstrate that by regulating the printing conditions, it is possible to generate different hydrogels starting from a single bioink solution, and the resulting bioprinted environment influences the cell proliferation.

METHODS: Silk fibroin solution including high-density human dermal fibroblasts was bioprinted into a solid hydrogel using a ruthenium-based cross-linked method and two-photon infrared laser polymerization. The resulting hydrogels were analyzed by SEM, FTIR and optical coherence elastography. The cells included in the hydrogels were cultured in vitro and their viability and proliferation rate were assessed up to four weeks using a live-dead assay.

RESULTS & DISCUSSION: Tuning the intensity of the two-photon infrared laser it was possible to regulate the mechanical properties, cross-link percentage and microstructure of the resulting hydrogels. Cells were observed to engraft within the hydrogel in a 3-dimensional way during a 4 weeks’ timeframe and proliferated from it, with a different rate depending on the hydrogel stiffness and cross-linking percentage.

CONCLUSIONS: This approach could be used to produce patterned silk biomaterials, capable of influence the cell behavior and proliferation, for soft tissue engineering and cell delivery.
Biofabrication of multiscale bone ECM scaffolds to support vascularization and osteogenesis

INTRODUCTION: Interconnected porosity is critical to the design of regenerative scaffolds, as it permits cell migration, vascularization and the diffusion of nutrients and regulatory molecules to the inner parts of the scaffold. 3D printing is a promising strategy to achieve this as it allows for control over scaffold pore size, porosity and interconnectivity. The aim of this study was to integrate distinct biofabrication strategies to develop multiscale bone ECM scaffolds that were not only mechanically functional at the time of implantation, but which also supported rapid vascularization and osteogenesis of recruited stem cells. To this end, 3D printing was used to control the macro-porosity of bone ECM functionalized scaffolds, while controlled micro-porosity was introduced by freeze-drying solubilized bone ECM within these 3D printed scaffolds.

METHODS: Decellularised bone (DCB) extracellular matrix (ECM) was generated as previously described [1]. 30% (w/w) DCB was added to PCL to generate a composite thermopolymer. Scaffolds of Ø 4mm x 4mm high, a fiber spacing of either 0.8 mm (70% porosity) or 1.2mm (80% porosity) were printed with PCL+DCB (macroscale porosity). Using the DCB a solubilised bone ECM (sbECM) was generated using pepsin and acetic acid. The sbECM was lyophilized in between the printed filaments of the PCL+DCB scaffold (multiscale porosity). Porcine MSCs (1x10⁶) were seeded on scaffolds 24 hours prior to subcutaneous implantation into nude mice. Microct (µCT) and quantitative histological analysis were assessed at 2 and 8 weeks.

RESULTS & DISCUSSION: For the macroscale porous scaffolds, a larger fiber spacing/porosity (80%) was found to accelerate vascularization compared to a smaller fiber spacing/porosity (70%). Furthermore, there was significantly more vessels present in the centre of the multiscale porous scaffold compared to the macroscale porous scaffold after 2 weeks of implantation.

CONCLUSIONS: We have developed a bone ECM derived scaffold that is mechanically competent and appropriately porous at multiple scales, thereby enhancing vessel infiltration and bone formation in vivo.

Use of tannic acid as a versatile tool for surface modification in tissue engineering

INTRODUCTION: Tannic acid (TA), a polyphenol, gathers several biological activities that are of particular interest in tissue engineering. Amongst them antimicrobial and antioxidative properties are the most cited [1]. It could be an interesting choice as well for biomaterial shaping or cell adhesion promotion due to its interaction with proteins [2-3]. Herein, we ventured to assess the influence of TA as surface coating agent on the adhesion, migration and survival of both fibroblasts and bacteria.

METHODS: Glass coverslips were coated with poly(2-hydroxyethyl methacrylate) (poly-HEMA) doped with various concentration of TA (0, 0.0078, 0.0625, 0.125, 0.25, 0.5, 1 mg/mL). NIH 3T3, mouse fibroblasts, were seeded at 25,000 cells/cm\textsuperscript{2} on such glass coverslips in 24 well plates and were allowed to attach for 4 h. Subsequently, the glass coverslips were transferred in a new 24 well plate to insure to discard non-attached cells. Cell adhesion, proliferation and migration were subsequently studied. Aside the same surfaces were challenged for antimicrobial activity as well as biofilm formation on Escherichia coli and Enterococcus faecalis.

RESULTS & DISCUSSION: NIH 3T3 adhesion is directly correlated to the concentration of TA incorporated in the poly-HEMA up to 0.25 mg/mL. Above, no cell adhesion is recorded. Cell adhesion is identical to a control surface with a number of focal point comparable. Adhesion is driven by direct interaction between integrin and tannic acid as demonstrated by adhesion test with culture medium without protein or surface modification by sodium periodate treatment. However, no substantial modification of the hydrophilicity was recorded by contact angle measurement whatever the concentration of tannic. Surface antimicrobial activity of TA is conserved once mixed to poly-HEMA, but under a threshold concentration (MIC = 100 \text{ug/mL}) bacterial adhesion is favored.

CONCLUSIONS: TA represents a versatile tool for surface coating that can favor eukaryotic cell adhesion and migration and, in the meantime, displays antimicrobial activity. However, the concentration must be tuned as over a threshold concentration, tannic acid is toxic for eukaryotic cell and above can favor bacterial adhesion and growth.

INTRODUCTION: We have previously shown that 3D porous scaffolds comprising of 40:60% chitosan/gelatin (CS/Gel) crosslinked with 0.1% v/v glutaraldehyde, promote the survival, proliferation and osteogenic differentiation of human bone marrow mesenchymal stem cells (hBM-MSCs) [1]. Herein we evaluate the production and composition of extracellular matrix (ECM) derived from hBM-MSCs following osteoblastic differentiation in CS/Gel scaffolds. Results were compared to respective hBM-MSC cultures in tissue culture polystyrene (TCPS) controls.

METHODS: hBM-MSCs were isolated from BM aspirates of healthy donors (n=6) after informed consent. The cells were ex vivo expanded until passage (P)-2, phenotypically characterized by flow cytometry and differentiated towards adipocytes and osteoblasts. Differentiation was assessed by specific mRNA gene expression and immunostaining. P2 hBM-MSCs were seeded on CS/Gel scaffolds and induced towards osteoblasts. We then assessed (a) hBM-MSCs adhesion potential by electron microscopy, (b) their osteogenic potential by mRNA expression of RUNX-2, DLX-5, OSC and ALP using real time-RT PCR, (c) the expression of ECM related genes using a PCR array and (d) the endogenous expression of osteopontin, osteocalcin and collagen type I A1 proteins using confocal laser fluorescence microscopy (CLFM).

RESULTS & DISCUSSION: hBM-MSCs were expanded successfully and fulfilled the minimal criteria for MSC definition (spindle-shape morphology, expression of CD90, CD105, CD29, CD73, lack of CD45, CD14, CD34 and ability to differentiate into adipocytes and osteocytes). Cultured hBM-MSCs on CS/Gel scaffolds showed strong adhesion potential and displayed increased osteogenic capacity as shown by the increased expression of ALP and OSC at days 7 and 14 compared to the TCPS cultures and the increased expression of RUNX2 and DLX5 time course during the differentiation. PCR array analysis showed differential expression of ECM-related genes between hBM-MSC cultures differentiated towards osteoblasts in CS/Gel scaffolds and TCPS controls. In specific, we found increased MMP1, MMP3, MMP9-13, MMP16, and VTN and decreased COL1A1 COL5A1, SPP1, THBS1-2, TIMP1-3 mRNA expression in CS/Gel scaffolds compared to TCPS. CLFM images showed collagen type I A1 and osteopontin production in both CS/Gel scaffolds and TCPS; osteocalcin, as a late marker of osteogenic differentiation, was identified at low levels in both CS/Gel scaffold and TCPS.

CONCLUSIONS: We have evaluated for the first time the ECM production by hBM-MSCs cultured on 40:60% CS/Gel scaffolds providing additional evidence that this biomaterial supports osteogenesis. Our results present a promising strategy using hBM-MSCs within CS/Gel scaffolds for bone regeneration.

INTRODUCTION: Diabetic foot ulcers (DFU) are chronic, non-healing wounds that often lead to lower leg amputation [1]. Fibroblasts differentiated from iPS-reprogrammed fibroblasts (iPSF - Generated in Garlick lab) produce a more pro-repair, matrix [2]. Our lab aims to use this matrix as a source material for scaffold fabrication for DFU treatment. This work explores techniques to enhance post-iPSF matrix production.

METHODS: 2D cultures were used to test matrix enhancement. Human pre- and post-iPSF were seeded at 16k and 64k/cm², and 0 – 100 μg/mL Ascorbic Acid (AA) was added to media. In 3D: collagen-GAG scaffolds (CG) [3] were used as a template to grow pre- & post-iPSF (500k/CG) and cultured with 2D-optimized media. Confocal images (DAPI/Phalloidin) and SafraninO were used to assess cell penetration and matrix production. Coll1, 3, 4, FN1, LAMA1 and 5 RNA (key structural protein genes) were analyzed via RT-PCR in 2D and 3D. Analyses were conducted at 0, 1 and 3wk (n=3). 2-way ANOVA (Bonferroni post-hoc) was used for statistical analysis.

RESULTS & DISCUSSION: 100 μg/mL AA boosts matrix production in both pre- and post-iPSF groups increasing Col3, Col4, LAMA5 RNA in 2D 3wk post-iPSF (p<0.05). Pre- or post-iPSF 3wk seeded CGs (3D cultures) had no observable differences macroscopically; but handling post-iPSF scaffolds revealed a lower surface friction. Post-iPSF were more elongated on the CG surface and fully penetrated the CG at 3wks. Histology confirmed post-iPSF fill the CGs by 1wk, producing matrix. Coll1,3,4; FN1; LAMA1,5 RNA are higher in post-iPSF at 24hrs (p<0.05); but not at 1 wk. Notably, post-iPSF Col3 RNA is higher at 3wk (p<0.05).

CONCLUSIONS: This work demonstrates the ability of post-iPSF cells to produce matrix in higher volumes than pre-iPSFs. Furthermore, we demonstrate the possibility of enhancing Col3 matrix production (pro-repair), in 2D and 3D. Ongoing work will confirm protein levels in the matrix. This matrix will ultimately be used for scaffold fabrication for DFU treatment.

INTRODUCTION: Tumor microenvironment (TME) heterogeneity and dynamics are scarcely replicated in vitro [1] making hurdle to obtain a reliable experimental model to study breast cancer. By inducing the assembling of a fibroblast-synthesized extracellular matrix (ECM), here we propose a 3D tumor micro tissue mimicking relevant cellular and extracellular events occurring in native cancers.

METHODS: Breast cancer micro tissues (BC-T) were obtained by seeding human breast fibroblasts within engineered porous gelatin microspheres in a suspension bioreactor. Fluid dynamic conditions were optimized to induce the assembly of a fibroblast-synthesized ECM. Porous gelatin microspheres were designed to degrade in concert with the assembly of new ECM molecules [2]. At 14 and 21 days HUVECs and malignant MCF7 cells were added respectively. Normal micro-tissues (N-T) were obtained in a similar way by using non-malignant (MCF10) breast cancer cells instead of MCF7. By means of both on-line multiphoton microscopy and immunofluorescence we studied the micro-tissues modification in terms of textural parameters and composition of ECM, and variation of vascular network architecture.

RESULTS & DISCUSSION: At 3 days after bioreactor cultivation, both BC-T and N-T (200 m in diameter) presented an abundant production of neo-formed collagen network. In the extracellular space fibronectin (FN), hyaluronic acid (HA) and capillary-like network (CLN) were also present. Despite to N-T, after 10 days BC-T displayed strong variation of the extracellular space. We found: (i) alterations of both textural [3] and architectural parameters of collagen network (i.e. collagen correlation length, polarization of collagen fibers); (ii) increasing of fibronectin, HA, MMPs; (iii) increasing of volumetric fraction and ramification points of CLN. Interestingly, malignant cells formed heterogeneous structures inside each BC-T (i.e. single file, solid strand).

CONCLUSIONS: BC-TP possess a reactive TME showing an in vivo-like activation. This, coupled with its sub-millimeter size, makes BC-TP a powerful platform for therapeutic candidates screening, in tissue on chip applications also [3].

INTRODUCTION: In tissue engineering, the aim is to fabricate materials capable of mimicking native tissue. For tissue engineered heart valves (TEHVs), this requirement means they must withstand constant opening/closing cycles, and also remodel and grow as required. Our approach combines autologous cells in a scaffold made of fibrin collagen and glycosaminoglycan (FCG), which we have shown to be a potential platform for developing a fully functional TEHV [1,2]. TEHVs generally lack the ability to form new elastic fibers, resulting in a reduced fatigue life.

We propose that elastic fiber deposition, or elastogenesis, can be induced by adding recombinant human tropoelastin lacking domain 26A to human vascular smooth muscle cells (hVSMCs) seeded in FCG scaffolds [3].

METHODS: hVSMCs were seeded in FCG scaffolds [1] and 10 mg/ml tropoelastin was added onto the scaffolds on day 1, with a second addition on day 7. Samples were collected on days, 3, 7 and 14 for dsDNA quantification, compression testing, dimensional analysis and RT-qPCR.

RESULTS & DISCUSSION: Elastic fibers were present in all samples treated with tropoelastin. A second addition of tropoelastin increased the elastic fiber coverage in the scaffolds. Cell proliferation and compressive modulus did not change by the addition of tropoelastin. No dimensional changes were observed in the scaffolds. A two-fold increase in elastin expression occurred by day 3 which has not been seen in previous publications.

CONCLUSIONS: The results from this study have shown that elastogenesis can be induced in hVSMCs by adding recombinant human tropoelastin lacking domain 26A in order to promote elastic fiber formation in FCG scaffolds. The amount of elastic fibers deposited was dependent on the content of ECM elastin-associated proteins. These promising results demonstrate the potential in this elastic fiber formation method, which may advance the fabrication of fully functional TEHVs with enhanced elastic recovery and fatigue life.

INTRODUCTION: Mechanical factors are able to influence biological processes according to a mechanism termed mechanotransduction. [1] There is a growing effort to recreate rheological properties of natural networks by exploiting synthetic polymers. [2] Chitosan is one of the most widely used polysaccharides for biomedical applications. [3] The present contribution describes an active network based on a semi-synthetic polymer, a lactitol-bearing chitosan derivative (CTL, also termed Chitlac), and a transient inorganic cross-linker, boric acid. CTL is bioactive vs. different cell types such as chondrocytes, osteoblasts and neural cells. [4-6]

METHODS: Rheological behavior of CTL upon treatment with boric acid was explored. Self-healing ability and responsiveness to different stimuli (i.e. temperature and the presence of small molecules) were investigated by rheological tests. Mouse fibroblasts (3T3) and pig primary chondrocytes were seeded in multi-well plates and were allowed to attach for 24 h. Subsequently, the medium was changed with CTL-based networks. In a parallel experiment cells were encapsulated into networks. Cell viability was evaluated by Alamar blue assay after 1 and 3 days.

RESULTS & DISCUSSION: An uncommonly high dependence in the scaling law between the zero-shear viscosity and the concentration of CTL emerged, pointing to interesting potential implications in the field of viscosupplementation. [7] Strain hardening effects and non-linear response to stress were noticed. [8] Such trends are considered as hallmarks of cytoskeletal and biopolymer networks. Obtained networks were able to self-heal after breakage. Notably, herein we report that CTL-boric acid gels are multi-responsive systems, whose mechanics can be tailored by different stimuli such as the presence of small molecules (e.g. glucose). CTL-boric acid networks resulted to be biocompatible toward two different cell models, namely pig primary chondrocytes and mouse fibroblasts.

CONCLUSIONS: CTL based networks resulted to be biocompatible, multi-responsive and able to self-heal after breakage. Furthermore, these networks displayed mechanical properties similar to natural tissues. Giving the peculiar properties of the obtained system, bioactivity of CTL could be linked to a mechanotransduction mechanism. These networks are promising candidates as in vitro mimics of natural active matrices and for regenerative medicine applications.

INTRODUCTION: In recent decades, the link between many diseases such as diabetes or pancreatitis and existing obesity has been uncovered [1, 2]. In vitro models of inflamed adipose tissue could help to gain insights into the development of the pathological condition. Moreover, such a model could be used to screen for new potential drugs to contain a further epidemic increase of related secondary diseases as far as possible. There are various current attempts on the setup of an adipose tissue model, however most of them are based on the use of animal derived sera which come along with the potential risk of contaminations and high batch-to-batch variations [3]. We aimed to set up an adipose tissue model under defined conditions by the development of a defined adipocyte medium. Furthermore, we sought to lift the model to an inflammatory state by the incorporation of an immunological component in form of macrophages.

METHODS: Mature adipocytes (MAs) and adipose-derived stem cells (hASCs) were isolated from human subcutaneous adipose tissue and encapsulated in 3D hydrogels based on methacrylated gelatin (GM). 3D constructs were built by the manual setup or by an extrusion based bioprinting process and crosslinked via UV radiation at 365nm. While isolated MAs were cultured in adipocyte medium, hASCs were differentiated to MAs for 14 days.

For the integration of an immunological component, a defined co-culture medium for adipocytes and macrophages was developed. Monocytes’ ability to differentiate to macrophages was evaluated in mono-culture. Consecutive a functional co-culture of mature adipocytes and monocytes was set up under defined conditions.

RESULTS & DISCUSSION: A 3D printed adipose tissue simulating an inflammatory state was successfully established. The defined medium led to a co-culture with cell-specific characteristics of mature adipocytes and macrophages. The inflammatory state was proven by the expression of cytokines like Interleukin 6. The adipose tissue model morphologically recreates the in vivo situation which was confirmed by histological and immunofluorescence staining.

CONCLUSIONS: An inflamed adipose tissue model was implemented for the first time. This represents a fundamental achievement for future applications of in vitro adipose tissue models in the field of drug development. Hence, the model provides great potential for meeting the challenges to alternative methods for animal testing and the transfer of the results will be of great value for other tissue engineering approaches.

INTRODUCTION: 3D approaches made of collagen-apatite materials have been targeted envisioning mineralized tissues applications. Direct mixing of calcium phosphates powder with collagen solutions or scaffolds immersion in simulated body fluid (SBF) are the most common methods. However, loss of efficiency has been reported, pointing to uncontrollable methods and long processing time, which might result in a limited bioactivity. Alternatively, we propose for the first time the in situ mineralization of Prionace glauca (blue shark) skin collagen (PGColl) and its use on inks for the 3D bioprinting of encapsulated cells envisioning the engineering of mineralized tissues.

METHODS: Collagen extracted from blue shark skin through an acidic method was solubilized in 10 mM HCL. To induce hydroxyapatite formation, calcium chloride and ammonium hydrogenphosphate were added as calcium and phosphate sources (Calcium-to-phosphate ratio =1.67), respectively. To prepare the cell-laden bioinks, 2% (w/v) PGColl was combined with 12% (w/v) alginate at the following volume ratios: 1:1, 1:2, 1:3 and only alginate (AG). The printing process was carried out using sterile material in a REGEMAT 3D dispensing system, at room temperature (25 ºC).

RESULTS & DISCUSSION: FT-IR and XRD analyses confirmed hydroxyapatite formation of the in situ mineralized collagen. The printed constructs using the different bioinks exhibited a homogeneously distribution of cells, which indicates a successful cell encapsulation. The intensity of the red signal (dead cells) decreased with alginate ratio, revealing the positive effect of mineralized PGColl with enhanced cell metabolic activity and proliferation (DNA quantification).

CONCLUSIONS: Successfully designed and printed cell-laden constructs made of in situ mineralized PGColl through a biomimetic approach were achieved. The survival and spread of cells were favored by the presence of mineralized PGColl.

INTRODUCTION: In-vitro bone tissue models are a prerequisite tool for a deeper comprehension of the biological mechanisms in bones [1]. Mineralized bone matrix formation as well as bone cell differentiation are essential requirements for reliable bone tissue models. In this work, a microengineered 3D cell culture system recapitulates the structural and biochemical microenvironment for human osteoblasts to mineralize a collagen matrix and differentiate to osteocytes. A bone on a chip approach will be a useful strategy to investigate the effect of mechano-chemical stimuli on bone cells response.

METHODS: Microfluidic devices were made of PDMS as describe previously [2]. Primary human osteoblasts (PromoCell) were seeded in rat tail type I collagen hydrogel (Dow Corning) at the final concentrations of 2.5x10^5 and 10^6 cells/ml and cultured up to 21 days with 10 mM β-glycerophosphate (Sigma Aldrich) and 50 μM ascorbic acid (Sigma Aldrich). DNA content, extracellular ALP activity assay, calcein staining, BSP2 and DMP1 immunofluorescent staining were conducted after 7, 14, 21 days. Live cell images were analyzed with a custom-made Python software to quantify protrusion length change over time, characteristic of osteocytic differentiation.

RESULTS & DISCUSSION: Osteoblasts expressed a mature phenotype during the 3D culture. They did not proliferate, expressed ALP, deposited calcium compounds on the matrix and produced BSP2. Mineral deposition was formed for both concentrations tested. For a cell density of 10^6 cells/ml, we measured longer protrusion length after 21 days of culture compared to day 7. In addition, other osteocytic markers increased as of the number of cell-cell connections and deposition of DMP1 on the extracellular matrix. On the other hand, cells culture d at 2.5x10^5 did not produce DMP1, confirming that osteoblast-osteocyte transition is regulated by cell seeding density [3].

CONCLUSIONS: These data show how microfluidic platforms can be used as in vitro mature bone tissue models, inducing specific bone matrix production (DMP1) to mimic the cortical bone environment with the differentiation of osteoblasts to osteocytes. The system is applicable for investigating the effect of fluid flow on 3D-cultured human bone cells.

ACKNOWLEDGEMENTS: The CuraBone project received funding from ITN-MSCA, grant agreement No. 722535.

INTRODUCTION: Biofabrication of complex hierarchical tissue structures relies on the development and progressive fusion of μTissue modules. During chondrogenic differentiation, μ-spheroids mature and secrete increasing amounts of glycosaminoglycan rich extracellular matrix to form μTissues. In this study, we investigated in vitro μTissue fusion and demonstrated that bioassembled constructs preserved their spatial properties in vivo. This was shown for both adult progenitor as well as induced pluripotent stem cells (iPSC) as cell source.

METHODS: Human periosteum progenitor cells (hPDC) or chondrocytes derived from iPSC (ch-iPSC) were seeded onto non-adherent agarose micro-wells resulting in cellular aggregation and μ-spheroids. These μ-spheroids were differentiated up to 3 weeks to form either hypertrophic-cartilage μTissues (hPDC) or cartilage μTissues (ch-iPSC). The μTissues were characterized with RT-qPCR and histology. Finally, two different bi-layered constructs were created and implanted ectopically in nude mice for 4 weeks.

RESULTS & DISCUSSION: Chondrogenic differentiation was up-regulated after 14 days for hPDC (14D) followed by hypertrophic markers after 21 days (21D) in culture. Histology further demonstrated accumulation of cartilaginous extracellular matrix (ECM) over time and metachromatic Safranin O staining after 21 days. These findings suggest that the μTissue maturation mimicked the process of endochondral ossification, as seen during long bone development. Spontaneous fusion was detected for all conditions with day 21 μTissues demonstrating slower fusion, indicating that the ECM maturation may interfere with the fusion process. Finally, two μTissue populations of distinct maturation levels (14D and 21D) were fused into a bi-layered cartilage construct composed of 2000 μTissues. In addition, a second bi-layered construct was formed using day 21 μTissues and iPSC μTissues. Both constructs further matured in vivo with maintained pattern into one cartilaginous and one mineralized part with bone.

CONCLUSIONS: Bi-layered hierarchical constructs maintained their in vitro engineered spatial features even after 4 weeks ectopic in vivo implantation. A complex osteochondral tissue was formed with layers directly correlating with the implanted tissue properties. These defined μTissue modules possess excellent properties for biofabrication of complex tissues through bio-assembly and -printing.

**Polyurethane scaffold for cartilage tissue engineering**

**INTRODUCTION:** Porous scaffolds are widely investigated for tissue engineering purposes. While the influence of pore size and porosity has been deeply studied [1], interconnections size (i.e the aperture connecting two pores) hasn’t been so much investigated. Herein, we generated polyurethane scaffold with well controlled pore and interconnection sizes, and looked at the influence of the interconnections on Wharton’s Jelly mesenchymal stem cells (WJMSCs) growth.

**METHODS:** Polyurethane scaffolds were generated using the so called “sphere templating” approach [2]; paraffin microbeads were generated by an emulsion, and subsequently sieved to select beads with diameter of 133±28µm. Beads were sintered at several temperatures and times to create a neck between adjacent beads. Polyurethane (FoamPartner, Swiss) was cast on the beads and filled the interstitial space between the beads and let to solidify. Paraffin was then dissolved in n-hexane to leave the porous structure. Scaffolds were then placed under plasma cleaner for 3min, 200mTorr in order to make the surface more hydrophilic. WJMSCs were seeded on each scaffold at a density of 1.10⁶ cells/scaffold.

**RESULTS & DISCUSSION:** Porous scaffolds were obtained with highly spherical pore shapes. Interconnection diameter were controlled through the sintering process of the paraffin beads, one having interconnection diameters of 27±10µm named as SMALL, and 52±12µm for the other (named as LARGE). Pore diameter was 133±28µm. DNA concentration was found significantly higher in scaffolds with LARGE interconnections specially for day 14 and 21. WJMSCs had a higher ability to spread across the scaffold with LARGE interconnections while cells remained isolated and mostly on surface for SMALL ones which prevented a good colonization of the whole scaffold.

**CONCLUSIONS:** These results underline that in interconnections diameter drastically influence the colonization of polyurethane scaffold by WJMSCs.

Drug-induced liver injury is one the most frequent reasons for drug failure at the clinical and post-marketing phases and is also among the main causes of acute liver failure in the USA and Europe [1]. Pre-clinical in-vivo animal studies, performed to evaluate the efficacy and safety of new potential drug candidates, are highly costly and time-consuming [2]. Therefore, in-vitro liver platforms for drug testing based on hepatocytes from different animal species might be a potent tool for high throughput screening to reduce in-vivo animal studies during drug development and lessen drug attrition rates and costs. Towards this end, various researches have shown the importance of combining multiple characteristics of the in-vivo hepatic environment to develop artificial liver systems [3]. Hence, the aim of the present study is to establish a functional porcine hepatocyte culture using a biofunctionalized 3D inverted colloidal crystal (ICC) hydrogel platform. The performances of non-adhesive bare poly (ethylene glycol) diacrylate (PEGDA) ICCs and PEGDA ICCs coated with either collagen type I or fibronectin were investigated. Porcine hepatocytes viability, morphology, hepatic-specific functions and patterns of gene expression were evaluated over a period of two weeks in culture to test diclofenac, a well-known hepatotoxic drug. A 3D cell culture environment, mimicking the hepatic lobular organization, together with the presence of extracellular matrix (ECM) proteins, especially fibronectin, led to different aggregation patterns and facilitated hepatocyte viability and maintenance of the liver-specific phenotype in vitro, enabling to the prediction of hepatotoxicity.

INTRODUCTION: Magneto-active coatings/scaffolds based on interconnected networks of ferromagnetic fibres have been proposed to promote the growth of peri-prosthetic bone [1-2]. When the scaffold is actuated in vivo by an external magnetic field, it deforms elastically as the ferromagnetic fibres tend to align along the field direction, imposing strains to in-growing bone tissue. Such deformation is known to promote bone cell growth provided the strains lie in the beneficial range [3]. The present work aims to generate in vitro proof of concept data of the osteoconductive potential of such magneto-mechanically actuated scaffolds.

METHODS: Human Osteoblasts (HObs) were seeded onto 85% porous 444 ferritic (magnetic) stainless steel networks and cultured in McCoy's medium. The magneto-mechanical actuation protocol, involved static culture for 7 days, followed by actuation for a period of 7 days using a sinusoidally varying magnetic field between 0.3 and 1.1 Tesla, at a frequency of 0.2 Hz for 4 hours (3000 cycles per day). Gene expression and protein expression were investigated using real-time Reverse Transcription Polymerase Chain Reaction (RT-PCR) and enzyme linked immunosorbent assay (ELISA).

RESULTS & DISCUSSION: An increase in osteogenic gene expression has been observed following magnetic actuation of ferromagnetic networks compared to non-actuated networks (control baseline). In addition, an immunoassay showed ~2 times higher BMP2 concentrations in cell culture supernates of actuated networks. Bone morphometric proteins (BMPs), especially BMP2, play a pivotal role in adult skeletal development and bone formation. The results are the outcome of three independent studies, no statistical differences were observed across the studies.

CONCLUSIONS: The results show an actuation-mediated upregulation of specific genes involved in the osteogenic lineage. Collectively, the proposed magnetic actuation strategy has the potential to promote osteogenesis.

INTRODUCTION: Biodegradable materials, such as polyglycolic acid (PGA) and polylactic acid (PLA), are used commercially in medicine for sutures, osteosynthesis systems and drug delivery systems and in research for meshes and tissue engineering scaffolds. In vivo hydrolytic degradation of PGA and PLA results in release of degradation products, which can cause local acidosis and lead to dramatic clinical complications. Incorporation of various additives (e.g. caffeine, tricalcium phosphate, calcium hydroxide, calcium carbonate, magnesium hydroxide, magnesium oxide) into PGA filaments for pH buffering failed due to insufficient buffering capacity and instabilities in the spinning process [1]. However, amine based microgels were shown to be a successful buffering agent for acidic degradation products [2,3]. These pH-responsive colloidal polymer networks are heat sensitive and therefore have to be incorporated into filaments using solution spinning. Incorporation of microgels into filaments by solution spinning and buffering of the pH value was successful. The spun filaments are inferior because of low tensile strength and high variation of tensile strength.

METHODS: In wet spinning trials monofilaments and multifilaments were extruded from PLA/chloroform solution into isopropanol and ethanol. Process parameters such as the quantity of incorporated microgels, spinneret geometry and polymer concentration in the spinning dope are evaluated. Mechanical characteristics are evaluated by tensile testing and morphology by light microscopy. Furthermore, the incorporated quantity of microgels in the fiber was determined by TGA measurements.

RESULTS & DISCUSSION: Tensile strength of wet spun PLA filaments is higher compared to dry spun PLA filaments. Round cross section filaments were produced. Wet spinning of PLA mono- and multifilament with 7 % incorporated microgels was successful, with a tensile strength of up to 14,9 cN/tex. A loss of 20 % of mass of microgels during the spinning process was observed. The effect of microgel incorporation on fiber morphology is small, however a significant decrease in tensile strength was noted.

CONCLUSIONS: Wet spinning showed to be a promising alternative solution spinning process, which allows production of microgel incorporated PLA filaments with round cross section and increased tensile strength.

INTRODUCTION: Male infertility is a substantial medical problem worldwide, often idiopathic. Due to the possible multifactorial nature of this disease, there is lack of effective therapy for the majority of male infertility cases. Thus, the strategy to recover spermatogenesis by targeting both spermatogonial stem cell (SSC) and their microenvironment called niche might be effective. Mesenchymal stromal cells (MSC) could be a promising tool to regulate SSC niche as these cells were shown to secrete a wide spectrum of paracrine factors supporting proliferation, survival and differentiation of cells in different resident stem cell niches. What is more important, MSC secrete molecules supporting functions and viability of SSC, Leydig and Sertoli cells. Thus, the study of efficacy and mechanisms of spermatogenesis restoration stimulated by MSC secretome might help to apply novel approaches for male infertility treatment.

METHODS: We developed the combined drug based on human MSC conditioned medium (CM) and collagen as a protective depo for MSC secreted components. Using a model of rat bilateral abdominal cryptorchidism for reversible SSC niche injury we observed that MSC CM effectively restored spermatogenesis. We applied immunohistochemical methods as well as morphometric analysis of contents of epididymes and serum testosterone concentration analysis to evaluate spermatogenesis recovery.

RESULTS & DISCUSSION: We observed that the injection of either MSC secretome combined with the collagen or MSC themselves recovered injured SSC niche. The numbers of primary and secondary spermatocytes in seminiferous tubules were increased. The total and moving spermatozoa numbers presented in the epididymes were also increased after the injection. Besides the recovery of germinal epithelium cells, we also showed the increase in Sertoli cell number and restrain of Leydig cell population growth. This might indicate important mechanisms associated with spermatogenesis recovery as a direct correlation between number of tubules containing a large number of proliferating cells and spermatozoa number, and an inverse correlation between the level of interstitial cell proliferation and spermatozoa fraction were revealed.

CONCLUSIONS: The application of MSC secretome combined with the collagen might be a promising approach to treat male infertility. MSC secretory function might be principal for spermatogenesis recovery as the beneficial effects of MSC as well as MSC secretome were comparable.

INTRODUCTION: The use of cell-derived matrices (CDM) is a promising alternative to decellularized tissues/organs as these are bioactive and biocompatible materials consisting of a complex assembly of proteins, growth factors and matrix macromolecules. 3D cell-cultured microparticles combined with macromolecular crowding (MMC) effect, offers the possibility to tailor-made bioactive materials for tissue engineering applications. We propose CDMs as potential colorectal tumor models for personalized medicine by mimicking tissue microenvironment properties [1].

METHODS: Human adipose mesenchymal stem cells are seeded at 100,000 cells/mg of PLA microparticles [2] in 24 well plates and cultured for 10 days under stirring conditions. Obtained CDMs are characterized by quantifying total protein and DNA, immunofluorescence staining of key components of CDMs, topography by SEM and gene and protein expression by qRT-PCR and WB. Besides, tissues are decellularized and particles are removed to be then recellularized in a perfusion bioreactor with colon cancer cells and cancer associated fibroblasts (CAFs) [3] to further characterize how cells remodel initial CDMs.

RESULTS & DISCUSSION: Addition of MMCs enhances protein deposition in CDMs. Fibrillar proteins collagen types I and III, which are highly present in colon tumor extracellular matrix (ECM), are over expressed after 10 days of culture. Tissues density and size is greater, and final tissue stiffness is increased. Cells and microparticles were successfully removed from CDMs, and their recellularization and cancer CDM characterization are taking place to finally produce an in vitro tumor model to understand cancer promoting mechanisms, to develop a patient-specific drug screening platform and to identify potential therapeutic targets.

CONCLUSIONS: CDMs composition, like expression of fibrillar proteins of the ECM, and the tunable matrix stiffness provides reproducible tissue microenvironment. By repopulating the tissue microenvironment with cancer and stroma cells, we have a promising platform for in vitro tumor model generation.

INTRODUCTION: Cell printing remains limited in the size and functionality of tissue that can be generated due to: (i) resolution, (ii) polymer content levels within bioinks and (iii) limitation in assembly of printed layers [1,2]. Herein, we detail a novel nanocomposite bioink based on Laponite nano clay (LAP) and gellan gum (GG) printed in a fluid-gel bath that enables skeletal biofabrication.

METHODS: LAP and GG were blended at 60 °C. Agarose fluid-gel support rinsed off immediately after deposition and crosslinking with CaCl₂. C2C12 myoblasts were encapsulated at 5 × 10⁶ cell ml⁻¹ and printed in agarose. Viability (live/dead) and functionality (alkaline phosphatase staining) were investigated at 1, 7 and 21 days. Printed and VEGF-absorbed samples were implanted on the chick chorioallantoic membrane (CAM).

RESULTS & DISCUSSION: LAP-GG hydrogel printed in agarose was able to produce high shape fidelity constructs resulting in a significant (p<0.0001) difference (322 ± 9 µm) in deposition resolution compared to in-GG printing (488 ± 9 µm). An increase in resolution was observed following LAP-GG printing in agarose compared to GG alone (p<0.0001). C2C12 were printed and remained viable in GG and LAP-GG composites, with a significant (p<0.0001) increase in proliferation and functionality for C2C12 printed in LAP-GG. VEGF in agarose was absorbed by LAP-GG and GG while printing and the resulting constructs were implanted in the developing CAM. LAP-GG-VEGF samples analysed after 7 days showed significantly enhanced vascular infiltration (p<0.01) compared to VEGF-free controls and GG-VEGF

CONCLUSIONS: LAP addition to GG bioink combined with a fluid-gel support resulted in enhanced printing resolution, promoting cell proliferation and drug (VEGF) absorption and localisation. The current studies demonstrate the potential of the suspended manufacturing platform to augment vasculogenesis in 3D cell-laden scaffolds with therapeutic implications for hard and soft tissue engineering.

INTRODUCTION: In bone tissue engineering, scaffolds are conceived to support cell proliferation and colonization by mimic the structure and the morphology of the surrounding native tissue. [1-3] Beside the architectural properties of scaffolds, other features are paramount to achieve the correct integration of the construct as the biocompatibility of the scaffold constituents and its degradation rate. The colonization process on one hand, and the differentiation of mesenchymal cells on the other hand, are influenced by the kinetics of nutrients and fluid exchange in the system. In this study we compared two culturing conditions: static and dynamic. The latter condition was achieved by means of a bioreactor. Effects of the culturing conditions were assessed on the proliferation and differentiation of human dental pulp stem cells.

METHODS: Human dental pulp stem cells (hDPSCs) were successfully isolated from third molars teeth extracted for orthodontic reasons from healthy patients under age of 35. Alginate-Hydroxyapatite (Alg/HAp) scaffolds were obtained as previously reported by our group [1,2] and loaded with lactose modified chitosan (CTL). hDPSCs were seeded (70,000cells/scaffold) on Alg/HAp-CTL scaffolds. Subsequently, scaffolds were randomly divided in two groups: static and dynamic. Static samples were located in incubator at 37 °C, and 5% pCO₂. Dynamic samples were cultured in a bioreactor with a medium flow rate of 100µL/min. Proliferation of cells was assessed with an Alamar Blue assay at days: 0, 1, 3, 5, 7. Differentiation of cells was evaluated with an Alizarin Red staining protocol.

RESULTS & DISCUSSION: Cells exhibited a proliferation behavior which was function of the culturing conditions. The proliferation rate of cells cultured in the bioreactor was significantly lower than the one exhibited by the cells cultured in static conditions. On the other hand, results obtained from the Alizarin Red assays indicated a more rapid differentiation of cells cultured in dynamic conditions if compared with the ones cultured in static conditions.

CONCLUSIONS: This work helped to shed a light on the culturing conditions of undifferentiated stem cells and how these conditions influenced both cells proliferation and differentiation. The setting of the culturing conditions is essential to predict in vitro the subsequent behavior of the scaffold once implanted in vivo. Future work will involve characterization of the scaffold structural behavior when stressed with dynamic flow.

INTRODUCTION: Tendinopathy represents a common and significant problem affecting people and animals alike [1-2]. While several animal models are used to study tendon pathologies [3], a comparison between different species in relation to human cells is lacking. The current study aims to report the differences and similarities of tenocytes response to inflammation in several in vitro animal models and human cells.

METHODS: Tenocytes from the Achilles tendon (mouse, rat and human) and the correspondent Superficial Digital Flexor tendon (horse and sheep) were used in the study. Primary cells from three donors per specie were included. Tenocytes were characterized upon acute (24 hours) and chronic (constant exposure) inflammation using 10 ng/µl IL1β and 10 ng/µl TNFα in comparison to unstimulated condition. Experiments were carried out to evaluate the proliferation capacity, gene expression profile and migratory properties of the cells. Proliferation was quantified by PicoGreen assay and proliferation rates were calculated in comparison to unstimulated condition after 24, 48 and 72 hours. Migration was evaluated through wound healing assay up to 96 hours. Finally, quantitative polymerase chain reaction (qPCR) was performed for several tendon and inflammation markers, as well as extracellular matrix degradation and production related genes.

RESULTS & DISCUSSION: The wound healing assay revealed similarity among all species. The migration capacity of the cells was reduced significantly upon inflammation, with stronger effect upon chronic inflammation. PicoGreen assays pointed out inherent differences between species. While proliferation rate decreased in sheep cells upon inflammation, in rats the opposite effect was observed. Moreover, the horse tenocytes increased proliferation upon acute inflammation while decreased upon chronic condition. Gene expression showed agreement between species in certain markers while other markers revealed altered trends in different animals. Similar trends in gene expression was observed in the small animals (mouse and rat) and in the large animal (sheep and horse) cells.

DISCUSSION AND CONCLUSIONS: It appears that tenocytes react to inflammation in a different manner in each species. In most aspects examined, small animals and large animals behave differently, however similarities could be seen between species inside each group. This work highlights the fact that none of the species behaves in the same manner as human cells in all aspects. However, it is also noted that each animal model is mimicking certain human tenocytes characteristics. Therefore, future studies should consider the differences shown in the current study, hence the animal model chosen to study inflamed human tenocytes should be selected with caution and in relation to the presented results.

INTRODUCTION: Bone tissue engineering is aimed at developing innovative biomaterials capable of promoting tissue repair. Herein, we developed a calcium functionalized silk gelatin-based 3D (SF-G-CaCl2) scaffold and evaluated the potential of enhancing the osteogenic differentiation of encapsulated human mesenchymal stromal cells (hMSCs).

METHODS: Silk gelatin-based 3D bioprinted constructs, composed of 5% bombyx mori silk fibroin (SF) and gelatin (G) were functionalized with 2.6 mM CaCl2 and encapsulated with hMSCs through the bioprinting platform (3D Discovery, RegenHU). SF-G was used as experimental control. SF-G-CaCl2 and SF-G constructs were cultured with D-MEM high glucose with and without osteogenic factors (GFs). Cell viability assessment and osteogenic differentiation through histology, gene expression analyses by Real Time PCR (RUNX2, COL1A1, ALP, OCN and SOST) and protein analyses by MALDI-TOF mass spectrometer (BMP-2, BMP-4, β-catenin) were carried out. 1, 14 and 21 days were chosen to monitor osteogenic differentiation.

RESULTS & DISCUSSION: SF-G-CaCl2 resulted biocompatible ensuring high percentage of cell viability. Histological analysis with von Kossa staining showed significant increase of mineralization deposition in the presence of calcium. Gene expression analyses displayed a high expression of RUNX2 and COL1A1 in 3D bioprinted SF-G-CaCl2 (P<0.01). The maximum level of ALP expression was observed for SF-G-CaCl2 at day 14. Moreover, hMSCs-laden SF-G-CaCl2 showed higher OCN and SOST expression compared to SF-G (P<0.001). Proteomic assessment gave evidence of an up-regulation of osteogenic signaling specific: BMP2 and BMP4 and β-catenin in SF-G-CaCl2 constructs.

CONCLUSIONS: We developed a 3D osteogenic environment based on a gradual calcium release that promoted the osteogenic differentiation of hMSCs at both gene and protein levels with the involvement of in vivo like signaling pathways. The advantages of combining Ca2+, SF-G bioink and 3D bioprinting technology opens potential insights for improving in vitro osteogenic potential of hMSCs for future BTE approaches.

¹ Center for Advanced Biomaterials for HealthCare@CRIB, Istituto Italiano di Tecnologia, Largo Barsanti e Matteucci 53, 80125 Naples, Italy ²Interdisciplinary Research Centre on Biomaterials (CRIB), University of Naples Federico II P.le Tecchio 80, Naples, Italy ³Department of Chemical, Materials and Industrial Production (DICMapi) University of Naples Federico II, P.le Tecchio 80; Naples, Italy ³Department of Veterinary Medicine and Animal Productions, University of Naples Federico II, Italy

INTRODUCTION:
A pre-vascularized skin can accelerate the formation of anastomosis in vivo ensuring the survival of the implant. In the same time, in vitro, it can be a suitable model in view of fundamental research and industrial applications like drugs screening. Here, we vascularize a dermis equivalent model in vitro and prove its ability to anastomose with host vessels in mouse.

METHODS: Human dermal equivalent was produced as previously reported [1]. For producing pre-vascularized dermis (PVD) HUVECs were seeded on a surface of the samples [2]. Confocal Multiphoton imaging was used to monitor in vitro vessel formation and collagen deposition. Animal studies were performed following the guidelines of EU (2010/63/EU). Six immunoincompetent nu/nu mice 6/7 weeks old were implanted with the PVD and six with the non-vascularized ones. Animals were sacrificed 1 week after graft implantation and the explants were fixed in formalin (n=3) and paraformaldehyde (n=3) for immunofluorescence and histological analysis.

RESULTS & DISCUSSION: Human dermal equivalent was featured by the presence of primary Human Dermal Fibroblasts (HDFs) embedded into their own extracellular matrix (ECM). Confocal imaging showed that HUVECs were able to form capillary like structures (CLS) having an inner lumen in 1 week. The molecular analysis showed that the evolution of CLS in vitro was guided by VEGF-A. CLS were totally embedded into the ECM rich in collagen produced by HDFs, and were featured by bifurcation as it occurs physiologically. In order to study tissue integration in vivo, after 9 days of in vitro culture the PVD was implanted subcutaneously on the back of nu/nu mice. The results indicated that capillaries were perfused in vivo and in turn proved the existence of functional anastomosis between CLS and host vessels.

CONCLUSIONS: We obtained a pre-vascularized dermis model with CLS positive for maturation markers from 1 week after Huvec seeding. PVD was easy-to-handle and to suture. In vivo results showed that CLS were able to anastomose with host vessels in 1 week and be perfused by blood ensuring the sustenance of the graft. Ongoing experiments are carrying on to develop a vascularized full thickness skin model for wound healing application.

INTRODUCTION: Basic and translational research has enabled improvements in the clinical management of osteoarthritis (OA). Recently, the adipose “niche” has emerged as a promising therapy being a rich source of progenitor cells available with different procedures [1-3]. Herein, we investigated the migratory potential of micro-fragmented adipose tissue (MFAT), stromal vascular fraction (SVF) and expanded- adipose derived stromal cells (ASCs) in a rabbit OA model to promote joint tissue repair.

METHODS: OA was induced in rabbits by anterior cruciate ligament transection. ASCs (n=6) and SVF (n=6) were obtained by enzymatic treatment using collagenase NB4, whereas MFAT (n=6) by a mechanical treatment in a one-step closed system (Lipogems). Cell were evaluated for their viability and characterized for specific mesenchymal markers. For local biodistribution analysis, cells were labelled with PKH26, a fluorescent dye. After OA onset, 2x10⁶ ASCs, SVF and MFAT were intra-articularly injected. Analyses on cell distribution and co-localization for PKH26 and CD-146 were done at short and long-term follow-ups: 7 and 30 days. The Monte Carlo method and the general linear model for multiple comparisons were used for statistics.

RESULTS & DISCUSSION: A good cell viability was found in all cell compounds showing high percentages for mesenchymal markers. Distinct and long-term migration was found for ASCs, SVF and MFAT. At day 7, ASCs and SVF showed a high tropism towards the synovium, whereas MFAT versus articular cartilage. Conversely, an opposite migration was found at day 30 for all cell compounds. Different percentages of CD-146 progenitors were found for all cell therapies up to day 30. Moreover, MFAT displayed a higher percentage for the M2 macrophage marker CD-163 when compared to SVF (P<0.05).

CONCLUSIONS: The long-term presence of adipose derived cells has a clinical significance, since it ensures a reservoir of progenitors capable of launching various repair processes on body’s demands. Moreover, the highest percentage of CD-163 in MFAT poses some biological premises on its superior healing potential for OA treatment.

INTRODUCTION: The transplantation of pancreatic islets currently represents a promising therapeutic option for the management of insulin dependent diabetes (1). During the isolation procedure, islets receive several stress that continue to occur during the pre-transplant culture period. The enzymatic digestion is a critical step to obtain functional islets (2). Moreover the culture of islets in Three-Dimensional Culture condition seems to maintain their organoid morphology; interesting results show also that the co-culture of islets with mesenchymal stem/stromal cells (MSC) improve viability and function and graft survival (3).

METHODS: Recombinant COL G (Class I) and COL H (Class II) blend are used to purify islets from rat. The Islet were cultured in Three-Dimensional (3D) type-I collagen gel in the presence or absence of stromal vascular fraction (SVF) isolated from rat adipose tissue. To assess insulin release the GSIS index insulin release from islets cultivated with glucose 16,7 and with 5,6 mM in different days were quantified. To follow the functionality of islets in vivo, we use the same collagen gel system in transplantation experiment into Streptozotocin (STZ)-induced diabetic rats.

RESULTS & DISCUSSION: We observed islets morphology for several weeks and we follow their function using Elisa Test. The results showed that islets cultured in 3D condition maintain the functionality up to 15 days (GSIS index more of 1,2; after that time islets started to reduce the insulin secretion in vitro. In in vivo experiment we show a reversion of diabetes in rat transplanted into the omentum with about 2000 IEQ (islets equivalent). Moreover, SVF were co-culture in 3D collagen gel in order to study the interaction between the islet and the SVF. We observe an increase number of SVF surrounding the Islet probably stimulated by factor secreted by them. We do not observe an increase of insulin secretion in presence of SVF.

CONCLUSIONS: We are able to revert type 1 diabetes in rat model using islets purified with recombinant collagenase and transplanted into the omentum with collagen hydrogel. Moreover the co-culture of SVF and islet can be used to study of interaction between pancreatic islets and adipose tissue cells (for example by inducing hypoxia).

INTRODUCTION: Terminal complement complex (TCC) was previously identified in herniated human intervertebral disc (IVD) tissues [1]. Here, we characterize TCC deposition in the different IVD regions and its correlation with distinct disc pathologies.

METHODS: Disc tissues were collected from healthy donors (Healthy, n=6, age 12±7), patients with scoliosis but no signs of disc degeneration (Sc, n=10, age 16±5), or with disc degeneration (DD, n=36, age 60±13, Pfirrmann grade 3-5). TCC deposition was investigated in different IVD regions: annulus fibrosus (AF), nucleus pulposus (NP) and endplate (EP). Randomly selected Sc and DD cells (passage 2-5) were analyzed for gene expression of complement regulators CD46, CD55 and CD59, inflammation markers, matrix proteins and degrading enzymes. TCC deposition was induced in vitro by IVD cells culture with 5% human serum (HS), and analyzed by ELISA. Culture in serum-free medium served as control.

RESULTS & DISCUSSION: Although TCC immunopositivity was observed with high variability, a significantly higher frequency of TCC+ cells was found in Healthy (young) and DD compared to Sc group (p<0.05). After cell expansion, CD46 and aggrecan were significantly down-regulated in NP cells of DD compared to Sc (p<0.05). An increase in TCC deposition was observed in presence of HS (p<0.05), but no differences were observed between DD and Sc expanded cells.

CONCLUSIONS: The data suggests that TCC is formed in IVD cells both in very young or strongly degenerated discs, which might correlate with vascularization. TCC deposition could be induced in vitro, confirming that IVD cells are not completely protected. Ongoing studies explore the functional relevance of TCC in DD as possible target for new therapeutic approaches.

INTRODUCTION: High molecular weight hyaluronan (hMwHA) is a key bioactive macromolecule of healthy synovial fluid (HSF) whilst also effecting osmolality1. We hypothesize that a hMwHA supplemented culture medium may better recapitulate the biological features of HSF present in the patients' intra-articular joints. Thus, our aim is to investigate the effect of physiological levels of hMwHA supplemented into culture media on the chondrogenesis of human mesenchymal stem cells (hMSCs) that would be present in a traumatic defect after marrow stimulation techniques such as microfracture.

METHODS: Bone marrow hMSCs at P3 were evenly seeded fibrin at 5x10^6 cells/150μl and retained within macroporous Polyurethane (PU) scaffolds. Control medium was serum free DMEM plus 1% ITS+, 1% Pen/Strep, 1% non-essential amino acid, 50μg/ml ascorbate-2-phosphate, 5μM ε-amino-caproic acid, 10^{-5} M dexamethasone (HA- TGFβ-). This media was further supplemented with 10 ng/mL TGFβ1 (HA- TGFβ+) or with 0.2% HA (HA+ TGFβ-) or both (HA+ TGFβ+). 1,800 kDa HA was added to simulate HSF concentration and viscosity (2.3 mg/ml)2,3. 1,000kDa HA was also added to the scaffolds of one group at 0.02% (HAS TGFβ+). Real time qPCR was done to investigate gene expression. Total DNA, sulphated GAG and Safranin O/Fast Green staining were evaluated.

RESULTS & DISCUSSION: The level of GAG per media synthesized by HA+TGFβ- group was significantly and consistently higher if compared with the control medium TGFβ free (HA- TGFβ-) and the standard chondrogenic media containing active TGFβ (HA- TGFβ+) within the first week of chondrogenesis (**p<0.005; *p<0.05). Exogenous hMwHA (HA+ TGFβ+) reduced the upregulation of the hypertrophic cartilage marker collagen X, normally induced by active TGFβ.

CONCLUSIONS: Collectively, these data illustrate the beneficial effect of hMwHA supplemented media on 3D hMSC chondrogenic culture. In the current climate of animal welfare and "3Rs", HA media, by mimicking in-vivo environment, can be helpful to reduce in-vitro artefacts, enabling more accurate prescreening of potential cartilage repair therapies.

INTRODUCTION: We used a combination of theoretical and experimental approaches towards self-assembling (S.A.) peptide rational designs. [1] [2] The cell attachment motif RGD and a key-role residue were projected to be incorporated to the S.A. central motif GAITIG in order to allow respectively cell adhesion and metal nanoparticle binding. [3]

METHODS: We monitored the assembly of the peptide-derived networks and their morphology through: X-ray diffraction, TEM, FESEM and AFM. Cell-culture experiments used for viability were: MTT assay and LIVE/DEAD test. An ultraprecise femtosecond (220 fs) laser was used to fabricate 3D fully biocompatible scaffolds via Multi Photon Stereolithography (MPS).

RESULTS & DISCUSSION: The designed RGD S.A. peptides proved to be appropriate building blocks to form higher order assembled networks. (Fig. 1). [2] Cys-containing S.A. scaffolds could be efficiently attached to a hybrid zirconia-derived composite in a 3D fs laser fabrication named “scaffold-on-scaffold” strategy for cell attachment (Fig. 2a). In addition, preliminary results indicate that S.A. peptides containing Tyr and Trp responded positively to 1P- and 2P- irradiation (Fig. 2b).

CONCLUSIONS: These S.A. peptides will subsequently be studied for in vitro and in vivo models as they are amenable to offer open-ended possibilities towards multifunctional tissue engineering scaffolds of the future. Especially, these multi-functional scaffolds in the form of hydrogel have found important involvements in heart regenerative medicine applications.

Figure 1: (Left) AFM analysis showed clearly fibril formation of the peptides. Figure 2: (Middle) 3D structures produced by the 2PP technique. Zirconia-based «scaffold-on-scaffold» sandwich. Figure 3: (Right) fabrication for soft-tissue engineering.

Self-assembled peptide hydrogels for accelerating the osseointegration period of dental implants
G. Onak1, O. Gökmen1, O. Karaman1*
1Department of Biomedical Engineering, Izmir Katip Celebi University, Izmir, Turkey
Presenting Author: Günnur Onak, gunnur.onak@ikc.edu.tr

INTRODUCTION: Osseointegration is described as formation of functional and structural connection between the surface of the dental implant and host bone [1]. Tissue grafts have widely been used to fill the defects between dental implant and host tissue to accelerate the osseointegration process. However, healing time after dental implant application would take several months. Self-assembled peptide hydrogels have been successfully used for regeneration of many tissues such as bone, cartilage, neural and blood vessel. One of the major limitations of using self-assembled peptide hydrogel on bone regeneration is their inadequate mechanical property and ability of inducing osteogenic and vasculogenic differentiation simultaneously. The objective of this study is to develop and characterize in situ multifunctional self-assembled peptide hydrogels in different concentrations and determine the efficacy of inducing osteogenic of mesenchymal stem cells with their functional epitopes to use in dental implant osseointegration process.

METHODS: KLD 12(KLDLKDLKLDL), KLD 12- EEEE and KLD 12-EEGGC were manually synthesized manually on 4-Methylbenzhydrylamine (MBHA) resin. KLD-12 powder was dissolved in PBS in a peptide concentration of 1%, 2% and 4% (w/v). MSCs were re-suspended in a complete culture medium, and the peptide solution was added to prepare a peptide/cells suspension, with a final peptide concentration of 0.5 %, 1% and 2% by diluting with the cell density of 10^6 cells/ml. Cell encapsulated peptide hydrogels were incubated in osteogenic medium. Calcium Assay, ALP Assay and DNA quantification assay were evaluated on KLD 12-EEEEE and KLD 12-EEGGC groups by 7d, 14d, 21d and 28d to compare the effect on calcium phosphate nucleation and osteogenic differentiation of human mesenchymal stem cells. Atomic force microscope (AFM) was employed to examine the inner structure of self-assembled peptide hydrogel. The viscoelastic behavior of the hydrogels was characterized by rheology measurement.

RESULTS & DISCUSSION: AFM results revealed that self-assembled KLD-12 peptide resembled nanofibril formation. It was observed that when the concentration of peptides was increased, mechanical properties such as compressive and shear modulus was improved. No significant difference in osteogenic differentiating parameters was observed between different epitope containing groups.

CONCLUSIONS: Self-assembled KLD-12 peptide hydrogels in different concentration was successfully produced. After determining ideal concentration in terms of mechanical properties and osteogenic differentiation capacity, modified KLD 12 peptide with osteogenic motifs will induced to support both bone tissue as well as taking the shape of defect by injection. This injectable multifunctional scaffold that will be developed could be used in clinics to accelerate dental implant osseointegration.

INTRODUCTION: Craniofacial bone is highly vascularized tissue and its repair and regeneration is challenging especially when the network of blood vessels is disrupted due to any pathology or fracture, which makes the healing extremely difficult. The traditional scaffold implantation does not induce angiogenesis (formation of blood vessels), instead it relies on inflammatory healing response that results in insufficient oxygen and nutrient supply, hence, resulting in non-uniform cell differentiation and cell death [1,2]. This project investigated the tailored chemistry approach to obtain nano ceramics with added functionality. Therefore, the aim of this project ventured to assess the potential of cerium doped ZnO for improved cell viability & vascularisation.

METHODS: Continuous Hydrothermal Flow System was used to synthesize cerium doped ZnO. Raman Spectroscopy, X-ray Diffraction, Transmission Electron Microscopy, Brunauer–Emmett–Teller (BET) was performed to analyze nanoparticle properties. Human Osteosarcoma Cells MG63 were used for Cell viability and VEGF release assay. 10,000 cells/cm² were seeded in 24 well plates and were allowed to attach for 24 h, followed by introduction of nanoparticle suspensions. Moreover, supernatant was collected for VEGF release analysis and 7-day study was performed, and cell viability was analyzed at Day 1, Day 3, Day 5 and Day 7, respectively.

RESULTS & DISCUSSION: Chemical characterization suggested successful synthesis of cerium doped ZnO. Transmission Electron microscopy and Brunauer–Emmett–Teller (BET) demonstrated that the particle size ranged from 60-90nm and possess rod shaped morphology. 7-day cell viability study revealed that the cerium doped ZnO are non-toxic. Furthermore, increased cellular activity was observed in presence of Cerium Doped ZnO.

CONCLUSIONS: The preliminary data illustrated the non-cytotoxic nature of cerium doped ZnO. It also revealed promising results to initiate vascularization, which is the pre-requisite for bone regeneration. Further investigation on release mechanisms and biocompatibility are in progress which will lead to additional understanding of future potential for craniofacial bone regeneration and vascularization.

INTRODUCTION: The capacity to secrete protective and biologically active mediators places MSCs among the most suitable tools for tissue regeneration. Studying mesenchymal stem cell (MSCs) responses to biomaterials provides evidences that their chemical, biophysical and/or mechanical cues have a deep impact on MSCs fate1. However, current strategies neglect the effect of materials on MSCs paracrine activities. The present study investigates whether bone-mimetic material (B-MM) could promote MSCs pro-regenerative secretome; especially on the production of angiogenic and osteogenic factors

METHODS: Bone-mimetic material (B-MM) made from inorganic calcium phosphate supplemented with chitosan and hyaluronic acid biopolymers was built-up using an automated spraying device2. Human MSCs were seeded in 24 well plates at 24 × 10^3 cells/cm² on UV-decontaminated B-MM and cultured for 21 days. Between 19th and 21st day of culture, MSCs conditioned media (MSCs-CM) were collected, and stored at -80°C. Cytokines, chemokines and growth factors release was quantified by ELISA and their activities were evaluated on human endothelial cells (ECs) and osteoblasts (OBs).

RESULTS & DISCUSSION: MSCs cultured on B-MM, composed of carbonated apatite, chitosan and hyaluronic acid biopolymers for 21 days, showed the formation of bone-like nodules. However, bone-like nodule arising from MSCs fibroblastic layers occupied only 8% of cultured area. The secretome analysis showed that B-MM significantly affects the production of soluble mediators required for bone healing and homeostasis. MSCs on B-MM decreased the production of IL-1, IL-6 and IL-8 inflammatory mediators and increased the release of PGE2, HGF, b-FGF and VEGF angiogenic growth factors, enhancing thus ECs chemotaxis, inducing ECs inflammatory profile, regulating neutrophils recruitment through an up-regulation of ICAM-1 and interestingly promoting ECs osteogenesis properties by up-regulating BMP-2. IL-1, IL-6, IL-8 and VEGF are reported to mediate, in dose-dependent manner, bone regeneration by promoting pre-osteoblasts proliferation and differentiation1. As for OBs cultured in osteogenic media, qRT-PCR experiments showed that MSCs-CMs up-regulate the expression levels of RUNX2, COL1A1 and ALPL over the time, however no boosting effect of OBs differentiation was observed as BGLAP, late bone specific marker, was not detected.

CONCLUSIONS: Our data provide, herein, evidences that the indirect crosstalk between MSCs and various cell types involved in bone regeneration might be finely regulated by B-MM.

Label-free intrinsic cathodoluminescence resolves spectral signatures of highly heterogeneous tissue isolated collagen scaffolds

H.M. Larsson1, M. Cantoni1, M.S. Zielinski1
Presenting Author: Hans Mattias Larsson, mattiashans.larsson@epfl.ch
1CIME, École Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

INTRODUCTION: Resolving complex tissue structures in situ become extremely challenging since different types of cross-linked collagens and interacting extracellular matrix proteins might be involved, and typical characterization techniques, such as histology, immunohistochemistry, scanning electron microscopy (SEM) or diffraction-limited optical methods based on fluorescence or second-harmonic generation (SHG) cannot provide unambiguous compositional information. Recent examples of applying material science techniques, such as SEM correlated with energy-dispersive X-ray spectroscopy (EDS), showed interesting results in characterization of critical insights in pathological processes in calcified lesions in cardiovascular tissues, and helped to identify typical amino-acid fragments of collagen fibrils in preserved prehistoric specimens. Here we show a similar approach based on the intrinsic cathodoluminescence (CL) imaging contrast.

METHODS: A state of the art quantitative CL-SEM microscope was used in label-free characterization of tissue-engineered collagen scaffolds. Mass-spectrometry was used to confirm the identified extracellular matrix proteins of the scaffolds in the CL-SEM analysis.

RESULTS & DISCUSSION: Presented SEM (Fig. 1a) and hyperspectral intrinsic CL (Fig. 1b) images of bovine collagen gel were obtained with 40 and sub-10 nm spatial resolution, respectively. High accuracy in localization of spectral auto-CL signatures specific to molecular composition of isolated collagen fibrils (Fig. 1c) was possible due to the excitation with a sub-4 nm electron beam probe size, and confined carrier diffusion lengths within the bioorganic material. Deconvolution-based analysis of such hyperspectral auto-CL images allowed to differentiate between bovine, rat and humanized collagens, as well as localize thin layers of human fibrinogen complex over a 200 μm field of view (FOV), confirmed by correlation with a mass spectrometry.

CONCLUSIONS: Overall, this spectrally resolved label-free technique provides quantitative information about material heterogeneity with a sub-40 nm localization accuracy, and appears to be a powerful tool in monitoring molecular distributions. Label-free intrinsic cathodoluminescence technology with its resolution close to an average size of a protein and molecular identification capacity should be of interest to the tissue engineering community.

Figure 1: a) SEM image of a bovine collagen gel sample, and (b) corresponding panchromatic auto-CL image, obtained with 550 nm spectral bandwidth. (c) Auto-CL spectra projection along a thick collagen fibril, marked with the black dashed line in (b). Each spectrum corresponds to a single pixel within the auto-CL image.
Quantitative imaging of the cell mechanical environment of 3D multicellular systems

INTRODUCTION: Cell-matrix mechanical interactions modulate cell fate decisions and multicellular organization and as such are important for tissue engineering. We have developed optical imaging procedures and computational algorithms to quantify cellular forces in 3D multicellular culture systems relevant for tissue engineering. Here we show their importance for the study of angiogenesis.

METHODS: 3D in vitro assays of vascular endothelial invasion in collagen hydrogels were optimized for live cell optical imaging by means of either confocal fluorescence microscopy or selective plane illumination microscopy (SPIM). SPIM provides fast 3D imaging of relatively large, multicellular systems with reduced phototoxicity, making it ideal for live cell imaging. Cell-matrix mechanical interactions during vascular invasion were quantified by means of novel traction force microscopy (TFM) algorithms. First, non-rigid image registration was performed to resolve 3D matrix deformations around invading sprouts. Second, cellular forces that were responsible for the measured deformations were quantified using an iterative, finite element based solution scheme that makes use of a novel physics-based regularization method.

RESULTS & DISCUSSION: We previously demonstrated the superior accuracy and robustness of non-rigid image registration for 3D matrix deformation calculation, based on the use of fiducial markers as well as collagen network imaging (by means of Second Harmonic Generation) [1]. Applying our novel TFM methods to invading angiogenic sprouts, we observe robust patterns of radially pulling forces around sprout protrusions. When interfering with actin turnover (by adding cytochalasin D), forces are diminished, in turn inhibiting vascular invasion. Time lapse imaging data revealed strong correlations between matrix deformations and protrusion dynamics.

CONCLUSIONS: Our 3D TFM methods enable to study cellular forces in 3D multicellular systems relevant for tissue engineering.

Despite advances in the regenerative medicine field, few therapies have progressed to routine clinical application, with a number of translational challenges to be addressed before therapies can be approved. Superparamagnetic Iron Oxide Nanoparticles (SPIONs) have a multifunctional role to play in addressing such challenges to develop and translate stem-cell based treatments. One of the main translational challenges we currently face is to understand and control cell fate after implantation. SPION labelling allows for magnetic manipulation of therapeutic cells to remotely activate, track and target cells in vivo by external magnetic field to address these challenges. Here, we aim to introduce novel magnetic devices and describe how such devices can be used to enable cell therapy translation.
Translation of synthetic electrospun patch to the clinic

INTRODUCTION: Rotator cuff tears are a common and often debilitating problem. Despite technical improvements in surgical procedures, post-operative re-rupture rates occur in around 40% of cases. A clear need exists for materials that are both mechanically strong, and also stimulate the endogenous repair process of tissue. An electrospun product has been developed to fulfill this need; a multi-component patch comprised of bioactive electrospun layers, bonded to a mechanically strong woven backing. Preliminary testing has shown a good safety profile and improved cellular responses both in vitro and in vivo. This biodegradable product is now in preparation for the first in-man safety and feasibility trials.

METHODS: The patch development process will be used as a case study to detail the transition of tendon biomaterials from academic research, to GMP (Good Manufacturing Practice) cleanroom manufacture, along with discussion of the gathering of preclinical evidence of safety and performance of the device. Adoption of ISO 13485:2016 Quality Management Systems: Requirements for Medical Devices, provides a practical foundation from which to address the regulations and responsibilities involved in medical device manufacture.

RESULTS & DISCUSSION: The patch is a class III medical device, made using novel production techniques - as a result, the regulatory burden is high. In the UK, applications to initiate the first in-man clinical trial are made to the MHRA (Medicines and Healthcare Regulatory Agency). Preclinical data supporting evidence of biological safety must be gathered into an Investigator’s Brochure for review by the regulatory authority. This will include information on: biological evaluation of the device, risk management, sterilization compatibility, device traceability, design control and evidence of manufacturing quality and consistency.

CONCLUSIONS: Novel biomaterials are frequently invented within an academic setting, however, translation of these materials to the clinic is often slow and problematic. Through dissemination of this case study, we intend to show some of the methods, and requirements for translating implantable electrospun biomaterials towards human applications.

ACKNOWLEDGEMENTS: This research was funded by the National Institute for Health Research (NIHR), the Medical Research Council the Wellcome Trust and the NIHR Oxford Biomedical Research Centre.
Decellularized porcine matrix as a multifunctional biomaterial for regenerative medicine

INTRODUCTION: Decellularized xenografts represent an alternative in regenerative medicine due to their preserved biofunctional cues and mechanical properties, which represent an advantage over polymeric scaffolds. Herein we hypothesized that a decellularized porcine graft would possess advantageous properties for tendon and soft tissue regenerative medicine.

METHODS: The biophysical, biochemical and biological properties of a decellularized porcine peritoneum (DPP) were compared to commercially available products. These included a collagen-GAG matrix (CGM), a collagen-cellulose matrix (CCM) and a decellularized ovine forestomach (OFM). Characterization was carried out as previously described [1] and cell response was assessed employing human tenocytes, macrophages, stem cells (ADSC), fibroblasts (ADF) and endothelial cells (HUVECs), depending on the clinical field of study.

RESULTS & DISCUSSION: DPP was compared to CGM, which is employed clinically in tendon procedures. DPP showed lower crosslinking ratio (p<0.05) and coefficient of friction (p<0.01), but higher mechanical properties (p<0.01). Tenocyte response in vitro showed cytocompatibility of DPP in means of cell proliferation and metabolic activity, which in the CGM were lower than the control (p<0.01). This was also observed in macrophages, which also presented a lower proliferation in response to CGM (p<0.05). CGM also triggered a higher shift to M1 phenotype as demonstrated by a higher proportion of elongated cells (p<0.01) and a higher level of TNFα (p<0.01). ADSC response showed a higher proliferation of the cells when seeded on DPP (p<0.01), where a change of morphology of the cells was observed. However, flow cytometry analysis with markers CD73+, CD90+, CD44+ and CD45- showed a maintenance of the stemness of ADSC after 21 days on both materials. DPP was also compared to CCM and OFM, commercially available wound dressings. SDS-PAGE showed DPP and OFM were shown to preserve soluble collagen type I. ELISA growth factors analysis also showed both OFM and DPP to contain FGFb, TGFβ and VEGF, although DPP with higher levels (p<0.05). The angiogenic effect of all three materials was observed in vitro with a HUVECs scratch assay employing conditioned media from each material. However, only media conditioned with DPP showed an angiogenic effect in an ex vivo aortic ring model (p<0.05).

CONCLUSIONS: DPP presents a lower crosslinking and preserves biofunctional cues that provide higher cytocompatibility than CGM, granting it with potential for tendon tissue engineering. In addition, it also could represent a stem cell delivery vehicle. The preserved biofunctional cues also grant DPP with potential for soft tissue applications.

INTRODUCTION: The tumour microenvironment (TME) is a diverse interplay between cancer cells, other cell types, extracellular matrix (ECM) and vasculature [1]. Self-assembling peptide hydrogels (SAPH) are a class of biomaterials gaining popularity due to their nanofibrous structure, tuneable properties and chemical definition [2]. This project aims to validate SAPH as a potential platform to support cancer cell growth and vasculature formation, mimicking many features of the in vivo TME.

METHODS: MCF-7 breast adenocarcinoma cells were encapsulated within PeptiGelAlpha-1 (Manchester BIOGEL, UK) at a density of 1x10^6 cells/mL and cultured for up to 14 days. Zymography and ELISA of MMP-2 were used to investigate cell-mediated remodeling and migration within the hydrogel. Oscillatory rheology was used to determine the mechanical properties of the hydrogels. Fluorescence imaging was used to determine the presence of a hypoxic core, while histological sectioning and Ki67 staining were carried out to investigate cell proliferation. Human umbilical vein endothelial cells (HUVECs) and mesenchymal stem cells (MSCs) were encapsulated within PeptiGelAlpha-1 alone and functionalized with 1%, 10% & 40% RGD to assess vascular tube formation capacity.

RESULTS & DISCUSSION: PeptiGelAlpha-1 alone was shown to support the viability and growth of MCF-7 cells up to 14 days. H&E staining of hydrogel sections showed the cells were dispersed throughout the hydrogel. Ki67 staining showing proliferation of the cells will also be presented. Oscillatory rheology and an MMP-2 ELISA assay were used to determine if MCF-7 cells were actively remodeling the matrix. Compared with PeptiGelAlpha-1 alone, functionalized SAPH stimulated the elongation and aligning of HUVECs and MSCs. Data on hypoxia will also be presented.

CONCLUSIONS: SAPH are able to support MCF-7 cell phenotype and viability and mimic features of the TME. The RGD binding domain within SAPH appears to enhance tube formation of HUVECs and MSCs.

INTRODUCTION: Biologic drugs revolutionized the treatment of autoimmune diseases (ADs). However, they present limited efficacy mainly due to their short half-life. This work used liposomes, the most successful nanodelivery systems in the clinic, to neutralize interleukin (IL)-23. IL-23 has a crucial role in the regulation of the cellular mechanisms involved in inflammation. Indeed, this pro-inflammatory cytokine potently enhances the generation of pathogenic TH17 cells that are central drivers of ADs [1]. Furthermore, liposomes can incorporate imaging agents, such as gold nanoparticles (AuNPs), conferring them monitoring functionality. Therefore, a theranostic nanomedicine strategy was developed to reduce the deleterious inflammation observed in ADs.

METHODS: Unilamellar liposomes (LUVs) of EPC, DSPE-PEG-Mal, Chol (1.85:0.15:1) and vitamin E (200:1) incorporating 20 nm AuNPs were functionalized with the anti-IL-23 antibody [2]. LUVs characterization included the determination of their size distribution (DLS), zeta potential (LDE), stability (DLS and LDE), morphology (TEM) and cytocompatibility in the presence of human articular chondrocytes (hACs) and human macrophages (THP-1 cell line). The maximum immobilization of antibody and the capture of IL-23 presented in the macrophage conditioned medium was assessed using secondary antibody unbound quantification and ELISA, respectively. To examine the effect of LUVs on the reduction of IL-17 production it was used PBMCs stimulated with CD3/CD28 beads, IL-1β and IL-23.

RESULTS & DISCUSSION: Liposomes were able to efficiently integrate AuNPs into their interior, displaying a homogeneous average size of 137 nm, a negative surface charge and a spherical shape. Moreover, the vesicles were stable for six months at pH 7.4 and 4 ºC. Cellular assays with hACs and human macrophages showed that LUVs are cytocompatible for the tested concentrations. The anti-IL-23 antibody was efficiently immobilized at the liposomes surface (82.1 + 8.4%) and captured 53.5 + 9.6% of the cytokine produced by activated macrophages. Finally, LUVs were able to neutralize IL-23 since a reduction on IL-17 production by activated PBMCs was observed.

CONCLUSIONS: The developed formulation was able to inhibit IL-23 effects, namely the production of IL-17 that shows the value of this strategy for ADs treatment.

INTRODUCTION: Human induced pluripotent stem cells (hiPSC) enable the generation of cardiomyocytes (CM) that can be used in the development of cardiac models for drug screening and new therapy development. However, these CMs present immaturity limiting its applications [1]. Several methods have been used in order to induce maturation of iPSC-derived CMs. There is evidence that cardiac extracellular matrix (ECM) can affect positively cell maturation and cell-derived ECM deposition, particularly when included in 3D tissue engineered cultures [1]. Hence, we aimed to induce ECM deposition and CM maturation by including cardiac ECM particles in iPSC-derived bioengineered cardiac 3D spheroids (previously developed in our lab [2]).

METHODS: iPSCs were differentiated into CM using an established protocol [2]. At day 6 of differentiation cardiac progenitors were aggregated using AggreWells (STEMCELL Tech.). Cell aggregates (with or without ECM particles) were in dynamic culture for 20 days. Briefly, biomaterial derived from cardiac ECM was pulverized into microparticles and incorporated in the aggregates in the aggregation step (1%w/v), after suspension in culture media and centrifugation. Beating cell aggregates were characterized after 20 days in culture.

RESULTS & DISCUSSION: CM only and CM+ECM after aggregation demonstrated viability and stability throughout culture period. Morphologically, CM+ECM aggregates presented ECM elements in the surface of the spheroids. Histological assessment demonstrated that CM+ECM aggregates are more cellularized and with superior ECM deposition of GAG (glycosaminoglycans) and Collagen per DNA. Immunofluorescence confocal microscopy corroborated this CM-derived ECM deposition, which was validated with GAG and collagen quantification, higher for the CM+ECM group.

CONCLUSIONS: ECM biomaterial functionalization was successful, with superior cardiac-specific ECM being deposited in the CM+ECM groups. This fact indicates that ECM with specific characteristics can be included in these relevant 3D spheroids and generate more representative and mature cardiac models.

INTRODUCTION: The growth of cultured cells is governed by factors in the surrounding microenvironment including the physical space in which cells occupy [1]. We have utilised three-dimensional (3D) and perfusion techniques to create a novel bioreactor system which aims to bring culture conditions closer to those found in vivo. The liver has been chosen for testing of the system as it is a complex and highly perfused organ and therefore models of the liver should benefit greatly from this method [2, 3]. The system is used as a platform for hepatic co-culture models using immortalised cell lines with the aim to allow such cells to have more physiological relevance and increase their value in drug development.

METHODS: The HepG2 line is a hepatocellular carcinoma cell line which is used extensively for studying liver metabolism and protein trafficking. In an attempt to enhance cell structure and function, we have developed a novel yet simple perfusion system which can be used for 3D culture of HepG2 cells in a more physiologically relevant environment. Further complexity is created through use of a supportive layer of fibroblasts and the addition of non-parenchymal cells such as endothelial cells.

RESULTS & DISCUSSION: Cultures of HepG2 cells in perfused Alvetex® culture show enhanced proliferation and viability compared to both 2D and 3D Alvetex® static cultures. An altered morphology is also seen with changes in the levels of cell-cell contacts and hepatocyte polarity. Growth on a fibroblast layer minimises cell invasion into the substrate and helps to minimise effects of shear stress on the hepatocytes, providing a homogeneous 3D tissue disc. This system was also found to be successful for maintaining the viability of precision-cut liver slices over prolonged periods, another technique which can be used for the modelling of the liver.

CONCLUSIONS: Introducing perfusion to 3D Alvetex® based cultures illustrates the potential for more physiologically relevant in vitro cell culture. Through this methodology we aim to create models which have improved structure and enhanced function compared to current assays, increasing the accuracy and predictive capacity of such models in drug testing.

INTRODUCTION: Osteoclast, which is differentiated from hematopoietic stem cells plays important roles in maintaining bone homeostasis through bone resorption. In the process of osteoclast differentiation, the topographic cue is one of the critical factors on the interaction between bone surface and cell [1]. Osteoclast precursor cell reacts sensitively to the surface which has rough topography through development of podosome, integrin-mediated adhesion structure [2]. However, for application to tissue engineering, well-defined topographic parameters are needed to study the control of differentiation of osteoclasts. In this study, we have examined the effect of microgroove patterns to induce osteoclast differentiation using murine precursor cells and the mechanisms involved in modulation of differentiation by surface topography.

METHODS: Microgroove patterned substrates were designed in line-shape with 2μm of width, 1μm of height and 1, 5, and 10μm of spacing respectively and were made of polydimethyl-siloxane (SILPOT 184, Dow Corning Toray) by soft lithography. Osteoclast precursor cells, isolated from bone marrow of Sprague Dawley rats were cultured on the substrates with vitronectin-coating (100 ng/cm²) in osteoclast differentiation medium at 37°C and 5% CO₂. Furthermore, to inhibit the activation of ROCK, MyosinII, and Rac1, cells were treated with 10µM of blebbistatin, Y-27632, and Rac1 inhibitor, respectively. After 4 days of culture, differentiated osteoclasts were determined via TRAP (Tartrate-resistant acid phosphatase) staining.

RESULTS & DISCUSSION: In differentiation medium, osteoclasts were observed in all substrates including flat surface without groove pattern by TRAP staining. As counting TRAP-positive cells stained in purple, the proportion of differentiated osteoclasts were most on the pattern spacing 1μm (p < 0.05 when compared to other patterns and p < 0.01 when compared to flat surface). In the presence of inhibitors, the osteoclast differentiation decreased significantly on 1μm (p < 0.01).

CONCLUSIONS: From this study, the effect of microgroove pattern, particularly spacing 1μm, was shown to promote osteoclast differentiation. Moreover, inhibitor experiments provided the possibility that precursor cell could sense the surface topographic while controlling the contractile stress via signal pathways that regulate actin stress fibers in the process of osteoclast differentiation. It is expected that these results will help to understand the process of cell differentiation by sensing the topography of bone surface, and furthermore, will be applied effectively to bone tissue regeneration.

INTRODUCTION: Additive manufacturing also known as 3D printing is about to revolutionize the field of dentistry. It allows the production of personalized surgical guides for oral surgery and endodontics. Furthermore, 3D printing is used to generate orthodontic devices including aligners, hard splints, retainers, and more. A key aspect for the clinical application of these devices is biocompatibility including the aspect of cytotoxicity. As part of the M3dRES consortium we evaluated the cytotoxicity of 3D printed Vero Clear, Vero Pure White, and the clinically approved Med610 printed in vertical and horizontal orientation.

METHODS: Specimens of Vero Clear, Vero Pure White, and Med610 were printed in vertical and horizontal orientation using the Stratasys Objet500-Connex3 system. The samples were then evaluated using scanning electron microscopy to reveal the surface structure. L929 cells, fibroblasts of the gingiva and dental pulp-derived cells were exposed to specimens of Vero Clear, Vero Pure White, and Med610 printed in vertical and horizontal orientation. The MTT and Toxdent assays were used to investigate the cytotoxicity of the material. Glass discs served as a negative control and carboxylate cement Durelon™ was used as a toxic positive control.

RESULTS & DISCUSSION: Scanning electron microscopy revealed surface structure differences between vertically and horizontally printed specimens. We found that Vero Clear, Vero Pure White, and Med610 did have a similar impact on viability as the not toxic negative control. The toxic positive control dramatically reduced viability. Vero Clear, Vero Pure White, and Med610 printed in vertical and horizontal orientation behaved similarly. This was found in L929 cells, fibroblasts from the gingiva, and dental pulp-derived cells. Interestingly, dental pulp-derived cells showed a higher variance with regard to their capacity of formazan formation than the fibroblasts from the gingiva or L929 cells.

CONCLUSIONS: Our results show that all three 3D printing materials Vero Clear, Vero Pure White, and Med610 do not show cytotoxic activity in our system with regard to L929 cells, fibroblasts from the gingiva or dental pulp-derived cells.

INTRODUCTION: In the context of cell-based regenerative medicine, exogenously administered mesenchymal stromal cells (MSCs) exhibited a poor survival rate. A possible explanation for this limited cell survival is that, upon implantation, MSCs encounter a harsh ischemic microenvironment characterized by low oxygen tension and nutrient deprivation. This issue can be overcome by in situ supplying glucose that acts as the main metabolic fuel for MSCs in hypoxia and enhances their survival. The objective of the study is to engineer a tissue-construct that provides sufficient level of glucose to MSCs and enhances their survival when transplanted in vivo.

MATERIALS & METHODS: To this aim, hydrogels containing fibrin, starch (a polymer of glucose) and AMG (an enzyme that release glucose from starch) were formulated. These injectable, self-supported hydrogels released glucose amounts in accordance with that required by hMSCs for their survival.

RESULTS & DISCUSSION: In vitro, under near anoxia, MSCs loaded in fibrin/starch/AMG hydrogels exhibited a survival rate 115 times higher than the one loaded in fibrin hydrogels, after 14 days. Moreover, when ectopically implanted in nude mice, luciferase-labelled hMSCs loaded in fibrin/starch/AMG hydrogels exhibited a significant improvement of their viability (x4 after 14 days) in comparison to hMSCs loaded in fibrin gels as demonstrated by the follow-up of the luciferase activity by bioluminescence imaging. These data were further substantiated by monitoring the number of hMSCs remaining in the hydrogels implanted ectopically in mice. At day 14 days, fibrin / AMG / starch scaffolds contained 7.5 times more viable hMSCs than fibrin hydrogels.

CONCLUSIONS: This work establishes for the first time that a construct based on a fibrin/starch/AMG hydrogel delivers glucose over time and enhances the survival of hMSCs. Most interestingly, the data obtained with hMSCs are now extended to adipose-derived MSCs and myoblasts.

Figure 1: (left) Hoescht and propidium iodide stained hMSCs maintained in hydrogels under near-anoxia. Figure 2: (right) Bioluminescence imaging and quantification of luciferase-labelled hMSCs loaded in fibrin and in fibrin/starch/AMG hydrogels, after subcutaneous implantation in nude mice.
A new formulation of porous injectable calcium phosphate cement foam for bone repair

INTRODUCTION: One of the challenges in bone tissue engineering with calcium phosphate cements is to create macroporous, degradable, injectable and bioactive materials. In this approach, the challenge is to incorporate encapsulated human mesenchymal stem cells (hMSCs) in a degradable cement to functionalize it. The goal is to maintain cells alive as long as possible to secrete bioactive factors for bone repair. Previously, a foam composite of calcium deficient hydroxyapatite (CDHA) and silanized hydroxypropyl methylcellulose (Si-HPMC) hydrogel with appropriate mechanical properties, injectability and porosity was developed. This previously used Si-HPMC hydrogel, that is poorly resorbable, was replaced here by silanized hyaluronic acid (Si-Hya Ac) hydrogel, that is biocompatible and biodegradable. All these materials were characterized. The thus obtained injectable cement foams are studied regarding their porosity, phase identification and mechanical behaviour.

METHODS: For the formulation of the cement, α-TCP and Na2HPO4 are mixed to form the cement’s phase of CDHA. α-TCP is synthetized at high temperature (1365°C) followed by very fast tempering. The hydrogel and the NaH2PO4 (with air) solutions are initially sealed in two commercial syringes, being ready for use. Directly after the mix, these two components (CDHA cement and Si-Hya Ac hydrogel) are mixed in the syringe and create the foam material. α-TCP is characterized by X-ray diffraction. The behaviour of different formulations of Si-Hya Ac are compared to Si-HPMC by rheology with the elastic modulus (G’), the maximum strength fracture and the resistance energy. Then the Si-Hya Ac is tested in the composite (Si-Hya Ac/CDHA) to find the same mechanical properties than Si-HPMC/CDHA. For this, the strength compression and flexion are compared. Finally, porosity with microCT are observed, and ionic interactions are investigated. Additionally, the biocompatibility and the cytotoxicity of all the component and the different composite formulations is studied.

RESULTS & DISCUSSION: This new formulation CDHA/Si-Hya Ac shows interesting biocompatibility and good mechanical properties compared to the reference CDHA/Si-HPMC.

CONCLUSIONS: The present study is a new route towards formulation of different and functional hierarchically porous cement using silanized polymers as foaming agent. The next step will be to compare the biological behaviours of the different formulations with and without encapsulated cells.

INTRODUCTION: Mesenchymal stem cells (MSCs) secrete a cocktail of growth factors and cytokines, which might be involved in the wound healing [1-2]. Herein, we compare paracrine profile of immortalised adipose tissue (at) MSC derived from chronic wound patient vs healthy donor and assess the influence of MSCs supernatants in in vitro model of chronic wound.

METHODS: Human atMSC were transfected with SV40 and hTERT plasmids to generate stable cell lines. Supernatants were produced by 24 h culture of MSCs in serum free media, (1% O2). Human skin cell lines: fibroblasts (MSU-1), keratinocytes (HaCaT) and endothelial cells (HSkMEC) were seeded in 96 well plates in serum free medium in hypoxic conditions (1% O2) that mimics chronic wound microenvironment. Cells were treated with different ratios of atMSC-supernatants (0, 10, 25, 50 and 100%) and serum free medium. Biological factors were assessed by human Cytokine Antibody Array. Cell morphology and metabolic activity (MTT) were assessed at day 0, 1, and 3.

RESULTS & DISCUSSION: Following immortalisation primary atMSC derived from chronic wound patient and healthy donor maintained their MSC phenotype which was confirmed by the expression of surface markers CD90, CD105, and CD73. Moreover, two clones of MSC of healthy donor were obtained. Analysis of the secretion profile of all four MSC lines confirmed presence of many biological factors involved in wound healing process such as VEGF, FGF, IL-8, MMP, GRO. Biological activity of atMSC supernatants was confirmed in vitro on fibroblasts, keratinocytes and endothelial cell lines. Microscopic evaluation and MTT analysis showed increase in all skin-derived cell survival in the presence of atMSC supernatants. Significant increase (p < 0.001) in metabolic activity of endothelial cells in the presence of supernatant from atMSC derived from chronic wound patient was observed as early as day 1 and was maintained during the next two days.

CONCLUSIONS: atMSC supernatants have beneficial effect on metabolic activity of different types of skin-derived cells involved in wound healing. Analysis of biological efficiency of all four supernatants revealed that concentration of 50% is the most effective on target cells metabolic activity.

INTRODUCTION: The human pluripotent stem cell is ideal source for tissue regeneration medicine. However, it is difficult to isolate differentiated/progenitor cells from undifferentiated cells on culture dishes. In this study, we used thermo-responsive polymers such as poly-N-isopropylacrylamide (polyNIPAAm), Poly(N-isopropylacrylamide-co-butylacrylate) (polyNIPAAm-co-BA), which have low critical solution temperature (LCST) around 20 degrees and are selected as the coating polymers on the cell culture dishes conjugated with different extracellular matrices (ECMs). With this smart biomaterials, we developed sorting dishes to isolate/purify human pluripotent stem cells-derived cardiomyocytes (hPSCs-derived-CMs) on the cell culture surface [1].

METHODS: PolyNIPAAm or polyNIPAAM copolymer were coated on 6 wells cell culture dishes conjugated with different ECMs (recombinant vitronectin (rVN) and Laminin-521 (LN-521). Cell culture dishes conjugated with ECMs were used as controls. Human pluripotent stem cells (hPSCs) were seeded and attach at first 24 h. Essential 8™ (Gibco) medium was changed every day. After hPSCs became confluence, the cells were induced to differentiate into CMs by using the JoVE and induction protocols developed in our lab. The CMs differentiation efficiency was evaluated by immunocytochemistry, beating colonies number, sarcomere length, and cardiac troponin T (cTnT) expression after 10 days.

RESULTS & DISCUSSION: We found on the polyNIPPAm surface coated with LN-521 (10μg/ml) has stronger affinity to CMs than coated with other ECMs. Surface marker cTnT was expressed higher for detached cells collected below LCST than non-detached cell. Flow cytometry assay shows cTnT expressions are higher than 90% after resoring. Furthermore, thermo-responsive polymer dishes coated with ECMs showed better cell attachment than TCPS dishes coated with ECMs directly. Our results also showed that hPSC-derived-CMs had higher survival rate on polyNIPAAm copolymer surface coated with rVN compared to dishes directly coated rVN on differentiation stage.

CONCLUSIONS: These data indicated the thermo-responsive polymer conjugated with LN-521 has potential to develop a sorting dish for purified CMs in hPSCs-derived-CMs cell culture.

INTRODUCTION: Reactive electrospinning is capable of producing in situ crosslinked scaffolds resembling the natural extracellular matrix efficiently with tunable characteristics. In this study, we aimed to synthesize, characterize and investigate the in vitro cytocompatibility of electrospun fibers of acrylated poly (1,10-decanediol-co-tricarballylate) (APDT) copolymer prepared utilizing photoreactive electrospinning process using ultraviolet radiation for crosslinking1, to be used for cardiac tissue engineering applications.

METHODS: The APDT pre-polymer was synthesized and characterized as reported by our research group1,2. The 3D elastomeric mesh was fabricated by means of assisted photo-reactive electrospinning (ES) using polyvinyl pyrrolidone (PVP) as chain entanglement enhancer. APDT with high molecular weight PVP in ethanol solution was prepared and stirred until a clear solution was obtained. The prepared solution was transferred to a syringe and was electrospun to produce an elastomeric mat via optimized electrospinning parameters. The polymer jet was crosslinked in situ using ultraviolet (UV) lamp that lead to the deposition of elastomeric electrospun matt on the collector. At the end of the ES process, the deposited fibers were left under UV for 10 minutes for complete crosslinking of any un-crosslinked residues. The produced scaffolds were fully characterized using different methods. Cell viability assay showed no significant cytotoxicity of the fibers on cultured cardiomyoblasts and cell-scaffolds interaction study showed a significant increase in cell attachment and growth on the electrospun fibers compared to reference.

RESULTS & DISCUSSION: Chemical, thermal and morphological characterization confirmed successful synthesis of the polymer used for production of the electrospun fibrous scaffolds with more than 70% porosity. Mechanical testing confirmed the elastomeric nature of the fibers required to withstand cardiac contraction and relaxation. Cell viability assay showed no significant cytotoxicity of the fibers on cultured cardiomyoblasts and cell-scaffolds interaction study showed a significant increase in cell attachment and growth on the electrospun fibers compared to reference.

CONCLUSIONS: The data support the successful preparation of photocrosslinked electrospun APDT based elastomers as promising scaffolds for cardiac tissue engineering applications.

Magnetically-responsive smart microparticles based on mussel adhesive protein for site-specific and prolonged drug delivery

H. Choi¹, Y. Jo¹, and H. Cha*

Presenting Author: HyunSun Choi, gustjs0419@postech.ac.kr
¹Department of Chemical Engineering, Pohang University of Science and Technology, Pohang, Korea

INTRODUCTION: Mussel Adhesive Protein (MAP) has superior adhesive property and biocompatibility, being exploited as a promising biomaterial. Magnetic force could be utilized for the targeted delivery of therapeutic drugs [1]. Therefore, we present magnetically-guidable sticky microferrogels in which therapeutic drugs could be site-specifically delivered and sustainably released during prolonged periods.

METHODS: MAP ferrogels were fabricated through microfluidic device-based water in oil (W/O) emulsion formulation [2]. In case of water phase, 15% (w/v) MAP in D.W, 1% (w/v) Fe₃O₄ and 30 mM genipin as a crosslinker, were utilized and for oil phase, FC-oil with 2% (w/v) surfactant was used. For the fabrication of the most monodisperse microparticles, flow rates of water and oil phase were optimized. In vitro cellular behavior analyses such as morphology and viability, MC3T3 fibroblasts were deposited on coated surfaces with MAP, genipin, Fe₃O₄, and their combination, respectively.

RESULTS & DISCUSSION: Genipin-crosslinked MAP ferrogels showed highly monodisperse shape and size, and robust mechanical property. The most monodisperse microgels were fabricated through flow rates of 5 ml/hr water phase and 20 ml/hr oil phase, and polydispersity index (PDI) of these ferrogels were 1.19%, which is much lower than 32.86% of conventionally fabricated microparticles. These uniform and monodisperse properties are beneficial for controlled and sustainable drug delivery according to target application. Particles size decreased as they were crosslinked from 123.1 μm to 53.6 μm. Due to magnetic force of Fe₃O₄ incorporated in particles, these particles could be guided toward permanent magnet, indicating these ferrogels could precisely deliver payload to specific location. In addition, MC3T3 showed spread morphology similar to negative control in all groups and cell viability also increased consistently with time. Therefore, we demonstrated that the MAP ferrogel system is biocompatible.

CONCLUSIONS: These magnetic-responsive sticky MAP ferrogels can be successfully exploited as promising drug carrier platform with enhanced controllability and robustness for localized and sustainable drug delivery.

The synergistic effect of topography and substrate rigidity in the development of a collagen scaffold for tendon tissue engineering

I. Sallent1,2, D.I. Zeugolis1,2

Presenting Author: Ignacio Sallent, ignacio.sallent@nuigalway.ie

1Regenerative, Modular & Developmental Engineering Laboratory (REMODEL), National University of Ireland Galway (NUI Galway), Galway, Ireland 2Science Foundation Ireland (SFI) Centre for Research in Medical Devices (CÚRAM), National University of Ireland Galway (NUI Galway), Galway, Ireland

INTRODUCTION: Biomaterial-based tendon implants are designed to withstand high physiological loads but often lack the appropriate biochemical, biophysical and biological structure to drive tendon regeneration by populating cells [1-2]. Herein, we ventured to create collagen I scaffolds that reproduce tendon natural anisotropy and rigidity, in an effort to engineer tendon tissue with native organization and strength.

METHODS: Porcine collagen I in solution was cross-linked with 4 arm PEG (4SP), poured on micro-grooved or planar PDMS moulds and dried to obtain imprinted collagen films. SEM/AFM and AFM indentation were used to analyse the surface topography and the rigidity of the scaffolds, respectively. Human tendon-derived cells were cultured up to 10 days and their morphology and ECM production was assessed by immunocytochemistry.

RESULTS & DISCUSSION: Precise control over the micro-grooved topography and the rigidity of the scaffolds was achieved by cross-linking the collagen with varying concentrations of 4SP at low pH and temperature. Human tenocytes cultured on the cross-linked collagen films aligned in the direction of the anisotropy for 10 days in culture. Synthesis, deposition and alignment of collagen III and tenascin C, two important tenogenic markers, were up regulated selectively on micro-grooved and rigid scaffolds, respectively.

CONCLUSIONS: Collectively, these results highlight the synergistic effect of anisotropy and matrix rigidity in the maintenance of the tenogenic phenotype in vitro. A precise combination of these biophysical cues in a collagen I scaffold will potentially lead to the design of smart biomaterials capable of driving cellular synthesis of organized tendon-specific matrix upon implantation.

ACKNOWLEDGEMENTS: Financial support was received from Marie Skłodowska-Curie Actions, Tendon Therapy Train (H2020-MSCA-ITN-2015-ETN), Grant Number: 676338.

INTRODUCTION: A scaffold directed to cell proliferation must have interconnected pores for molecular communication and spaces that allow the matrix expression. Tissue engineering in bone and cartilage are essential to provide regenerative therapies for osteochondral defects in osteoarthritis, a public health issue [1-2].

METHODS: The PLDLA was obtained by bulk polymerization reaction in the ratio 70:30 of the monomers L-lactide and D, L-lactide under vacuum at 130° C. Subsequently the pores of the scaffold were obtained by solubilizing PLDLA with 1,4-Dioxane at 40% (m/v) followed by freezing the solution at -20° C for 12 hours and sublimation of the solvent in Liotop® K105 Freeze-dryer at -90° C for 48 hours. The scaffold was submitted to morphological analysis by Scanning Electron Microscopy (SEM). Human Mesenchymal Stem Cells (hMSC) were cultured in the scaffold in Gibco® Dullbecco's Modified Eagle's Medium (DMEM) supplemented with fetal bovine serum (FBS) and Antibiotic Antimycotic Solution Sigma® at 1x10⁴ hMSC/cm³ for 7, 14 and 21 days. The hMSCs were submitted to differentiation with Gibco® StemPro Chondrogenesis Differentiation Kit (SPCD) and StemPro Osteogenesis Differentiation Kit (SPOD) at initial cell density of 4x10⁴ hMSC/cm³ both groups for 21 days. The samples were fixed in paraformaldehyde (PFA) and processed for analysis by Confocal Laser Scanning Microscopy (CLSM). The hMSCs nuclei were stained with Fluoroshield-DAPI, while the chondrogenesis differentiation group were identified for aggrecan by indirect labeling using Alexa-Fluor®647 as fluorescent dye and osteogenesis differentiation group were identified for osteopontin by indirect labeling with the same fluorophore dye.

RESULTS & DISCUSSION: The SEM microarchitecture obtained in scaffolds was composed of ellipsoid pores measuring 43.87 ± 68.49μm (minimum diameter) and 75.80 ± 116.95μm (maximum diameter) interconnected by canaliculi. The hMSC cultured with DMEM showed cell migration and proliferation forming a net inside the scaffold pores and the interconnected canaliculi. In SPCD culture was evidenced after 21 days high density cells in deeper areas in scaffold and strong aggrecan labeling. In SPOD culture after 21 days was visualized cell integration in scaffold and deposition of osteopontin and calcium nodes, as white points, typical of bone matrix.

CONCLUSIONS: The microarquitecture of the PLDLA scaffold has remarkable characteristics to allow cell proliferation, differentiation and matrix deposition. The results of cell culture and differentiation corroborate the applicability of this scaffold in the tissue engineering for osteochondral regeneration.

INTRODUCTION: Gene-activated bone substitute (GABS) is a complex of biocompatible scaffold and gene constructs encoding osteoinductive factor(s) [1]. We developed GABS based on octacalcium phosphate and plasmid DNA carrying gene of vascular endothelial growth factor (VEGF), called “Histograft”, and completed world’s first clinical trial (NCT03076138).

METHODS: The purpose of this study was to evaluate the safety and efficacy of the GABS “Histograft” (granular form) in treatment of patients needed bone grafting procedures. 20 patients aged 18±65 with acquired maxillofacial bone defects and alveolar ridge atrophy were enrolled in the clinical trial with the follow-up 6 months. As a primary outcome measure, we determined the quantity of newly formed bone tissue on CT scan using special tools (“ROI”, region of interest, etc.): average density (in HU); size (length, width, height) and volume.

RESULTS & DISCUSSION: All 20 patients (6 men, 14 women, 46.6 ± 11.9 years) completed the study. The indications for bone grafting with “Histograft” included upper jaw alveolar ridge atrophy (16), periodontitis with teeth removal (2), radicular cyst (1), peri-implantitis (1). GABS implantation was as simple as any other bone substitutes in granular form. Neither adverse nor serious adverse events were detected in the clinical trial. The postoperative period in all patients was uneventful; clinicians removed the sutures in 10 days after surgery. According to CT, the tissues with an average density of 908.13 ± 114.40 HU filled the bone grafting area. The volume of augmentation corresponded to the volume of the GABS implanted. 6-8 months after surgery, when the patients completed the clinical trial, majority of them underwent dental implants placement in the bone grafting area, and prosthetics were performed. In all cases trephine biopsies were harvested during dental implants placement and newly formed bone tissue was detected around partially resorbed GABS granules.

CONCLUSIONS: The clinical trial proofed the safety and efficacy of the GABS “Histograft” for bone grafting. However, more clinical data including comparative studies are needed to define the range of possible medical indications where the GABS could show a beneficial effect.

INTRODUCTION: Parkinson’s disease (PD) is a degenerative disorder that affects dopaminergic neurons in substantia nigra. Recently, cell therapy has emerged as a promising therapeutic strategy, with biomaterials being used to facilitate the cell deposition through intrastratial injection. However, the existing delivery approaches have shown limited success in clinical translation. This study aims to develop a device for the delivery of a cell-embedded in situ forming collagen hydrogel. Here, computational approaches on the delivery of collagen to the striatum are presented, to gain insight into different parameters affecting the delivery.

METHODS: The delivery of collagen was modelled computationally in the two-dimensional space. The striatum was modelled as a circular space, with an area of 3.98 cm² corresponding to the mean volume of putamen in PD patients. Within the finite volume method framework, the Volume of Fluid (VOF) method was used, assuming two isothermal and immiscible fluids. The collagen flow was considered incompressible, with non-Newtonian fluid behavior characterized experimentally, and constant inlet velocity corresponding to a maximum delivery volume.

RESULTS & DISCUSSION: The interaction between the collagen and the brain tissue phases was analyzed, using two types of needle tips, a blunt needle tip and bevel needle tip (Fig. 1A, 1B). Alpha indicates the phase distribution, with a=1 indicating collagen, a=0, brain tissue and 0<a<1 indicating the interface. The effects of collagen injection on the pressure fields within the striatum were also examined (Fig. 1C, 1D). A difference in the pressure between the two needle tips was observed, with the bevel tip showing higher pressure on the site of the delivery.

CONCLUSIONS: The intrastratial injection of a hydrogel is a complex process and computational analysis of the delivery can help identify the obstacles facing clinical translation. Further analysis is required including 3D reconstruction from MRI images and modelling in the three-dimensional space.

Figure 1: Two-dimensional model of collagen delivery to the striatum. (A) Interaction between collagen and brain tissue when injected with a blunt tip and (B) a bevel tip. (C) Pressure distribution for collagen injected with a blunt tip and (D) a bevel tip.

INTRODUCTION: The field of Regenerative Medicine and Tissue Engineering seeks to build functional tissues ultimately replacing failing organs, thereby curing the patient. The ability to produce large populations of small functional tissue niches that could be used for bottom-up assemblies of larger tissues would constitute a major step towards addressing this bottleneck. This could be achieved by providing a living engineering medium able to yield predictive results upon implantation.

METHODS: Human periost derived cells were seeded on non-adherent agarose microwells resulting in controlled cell aggregate populations containing 200 cells per unit. These were differentiated chondrogenically for 3 weeks. Media were changed every 3 days. Upon maturation these modules were fused into larger scaffold free implants and evaluated for bone formation in nude mice both ectopically and orthotopically. RNA seq analysis was carried for 7,14, 21 days as well as immunohistologic analysis.

RESULTS & DISCUSSION: We produced, in a scalable manner, thousands “cartilage intermediate” microtissues. Cells in these microtissues appeared to undergo developmental processes in vitro mimicking those encountered in the embryonic growth plate and during fracture healing in vivo. Upon reaching a degree of “autonomy”, as defined by genomic comparison to developmental controls, these microtissues were able to continue their biological program upon implantation, resulting in the formation of bone organs without inappropriate contaminating tissue structures. This capacity was robustly exhibited independent of the implantation site. Strikingly critical size murine long bone defects (5 mm) were healed within natural physiological time scales with the development of a de novo bone marrow compartment while in all cases abundant implanted cells were present, demonstrating their critical role in the regenerative process.

CONCLUSIONS: With these advancements, we believe that we contribute towards establishing ‘design specifications’ scalable engineered skeletal implants. This paves the way for the mitigation of unmet clinical challenges of large non healing tissue defects such as critical size bone non-unions. The µtissues could be viewed as a living ‘bioink’ allowing bottom up manufacturing of multimodular tissues with intricate geometric features and inbuilt quality attributes.

INTRODUCTION: The HPAE-EB cationic polymer family can electrostatically bind DNA, RNA and proteins to formulate <250 nm polyplexes showing high cellular uptake and release of the condensed nucleic acids and proteins in a triggered manner. Degradation via hydrolysis of ester groups in the HPAE-EB backbone allows release of nucleic acids and minimizes potential cytotoxicity due to intracellular accumulation post transfection. HPAE-EB has been proved to efficiently transfect GFP DNA in a wide variety of cell lines showing higher viability than other commercial reagents (jet-PEI and Lipofectamine 2000) [1]. Here we confirm efficient transfection using different systems for the treatment of Recessive Dystrophic Epidermolysis Bullosa (RDEB), an uncurable rare skin disorder caused by mutations in the COL7A1 gene which encodes collagen VII.

METHODS: The HPAE-EB polymer was complexed with non-integrative plasmids containing the full 8.9 kb COL7A1 cDNA including a) pcDNA3.1-COL7A1 (14.2 kb), and b) minicircle-COL7A1 (11.9kb), both using different promoters, and gene editing systems such c) CRISPR/Cas9 (9.4 kb) and d) RNP CRISPR (2 sgRNA plus Cas9) systems, both encompassing a double guide RNA strategy to mediate an exon skipping approach [2] over pathogenic mutations, and assessed for toxicity, efficiency and collagen VII synthesis/correction in RDEB Keratinocytes (RDEBK). Viability and efficiency were assessed 48hrs post transfection by AlamarBlue assay and GFP detection. Cells for flow cytometry were harvested, RNA for RT-qPCR, genomic DNA for PCR and sanger sequencing and protein for Western Blot. RDEB human skin graft mouse model was treated topically with HPAE-EB pcDNA3.1-COL7A1 to confirm in vivo efficiency.

RESULTS & DISCUSSION: GFP signal using gWIZ GFP, minicircle-COL7A1 or CRISPR/Cas9 at 30:1 ratio (polymer:DNA) shows the efficiency and cytocompatibility of the transfections, achieving in vitro genomic correction mediating exon 80 skipping and in vivo recombinant collagen VII.

CONCLUSIONS: The results show that the HPAE-EB polymer is a suitable gene delivery vector that can successfully work with very different systems, condensing and efficiently delivering topically large plasmids as well as in vivo for RDEB gene therapy.

INTRODUCTION: The use of fibrous proteins as keratin has been recently explored to improve the biological properties of scaffolds in tissue regeneration [1]. Electrospinning is one of the most recognized technologies able to confine - at the level of single fiber - a self-adapting pattern of morphological, chemical or physical signals to reproduce a functional ECM-like micro-environment. Herein, fibers made of Poly ε-caprolactone (PCL) and wool keratin will be investigated to evaluate the contribution of chemical and morphological features at in vitro epithelial cell behavior.

METHODS: Bicomponent fibers were processed via electrospinning by combining keratin - extracted from wool by sulphitolysis- and PCL into a unique solution. Electrospinning conditions were optimized in order to fabricate keratin added fibers without beads and/or defects. Morphological features i.e., average diameters and fibre distribution was investigated via SEM supported by image analysis. In order to in vitro validate the scaffolds, hMSC and HaCat cells were seeded onto PCL and keratin/PCL fibers to compare the viability until 14 days. Cell morphology was also evaluated by SEM microscopy, while new collagen formation was estimated by Sirius red dye at 14 and 21 days. The presence of cytokeratin markers was finally evaluated by immunofluorescence.

RESULTS & DISCUSSION: Electrospinning was optimized to form wool keratin and PCL composite fibres. The feasibility of the process was basically proved by ATR-FTIR analysis. Clear peaks for amide groups into the spectra confirm the presence of keratin into the fibers, without any alteration due to the electrostatic forces interactions during the process. The presence of keratin also induced an increase of the average diameter -144.1 ± 43.9 nm- respect to those of PCL fibers -81.7 ± 26.7 nm-. The increase in fibre wettability due to the presence of the hydrophilic protein, explained the improvement in cell adhesion in comparison to PCL fibres, used as control. SEM images on cell-seeded samples underlined a higher tendency of hMSC to spread in the presence of keratin along the fibers corroborated by roliferation progressively increased until 14 days. The bioactive effect of keratin was also confirmed by the higher formation of ex novo collagen in vitro after 14 and 21 days while the presence of cytokeratins was confirmed by fluorescence microscopy.

CONCLUSIONS: In this work, fabrication of PCL/keratin nanofibers was optimized to explore the potential use as cell-instructive scaffolds, with improved biological properties, due to the mutual effect of physical and biochemical cues. They promise to be a good candidate to regenerate epithelial tissues such as cornea.

INTRODUCTION: On the road toward the use of extracellular vesicles (EVs) for regenerative medicine, technological hurdles remain unsolved: high-yield, high purity and cost-effective production of EVs.

METHODS: Pursuing the analogy with shear-stress induced EV release in blood, we are developing a mechanical-stress EV triggering cell culture approach in scalable and GMP-compliant bioreactors for cost-effective and high yield EV production. The 3rd generation setup allows the production of up to 300 000 EVs per MSC, a 100-fold increase compared to classical methods, i.e physiological spontaneous release in depleted media (around 2000 EVs/cell), with a high purity ratio 1x10\(^{10}\) p/µg.

RESULTS & DISCUSSION: We investigated in vitro the regenerative potential of high yield mechanically-induced MSC-EVs by demonstrating an equal or increased efficiency compared to classical EVs with the same amount of EVs. The regenerative properties of mechanically-induced MSC-EVs was confirmed in vivo in a murine model of chronic heart failure demonstrating that high, medium shear stress EVs and serum starvation EVs or mMSCs had the same effect using local injection. We later tested the effect of the injection route and the use of xenogenic hMSC-EVs on their efficiency in the same model of murine chronic heart failure. Heart functional parameters were analyzed by ultrasound 2 months post infarction (1 month post EV injection).

Interestingly, hMSC-EVs had the same effect compared to mMSC-EVs in local injection, showing that xeno-EVs in immunocompetent mice were well tolerated. Moreover, hMSC-EV IV injection was as efficient as local intra-myocardium muscle injection with an increase in the left ventricular ejection fraction of 26% compared to pre-treatment values, whereas PBS injected controls lost 13%. High yield hMSC derived mechanically-induced EVs are therefore interesting candidates for simple IV injected regenerative therapies.

CONCLUSIONS: We demonstrated an equal or superior regenerative effect of high yield mechanically-produced EVs compared to spontaneously-released EVs or parental cells in vitro and in vivo, and good tolerance and efficacy of hMSC EV both with IV and local injection. This unique technology for EV production combines decisive assets for clinical translation of EV-based regenerative medicine: a GMP-compliant setup, high density cell culture, high yield release of EVs per cell, high purity EVs.
Differentiation of endothelial cells and smooth muscle cells in bi-layered vascular grafts under flow perfusion

INTRODUCTION: Here we present a fabrication approach for bi-layered vascular grafts, inspired on the native architecture of small diameter vessels with a confluent endothelium on the luminal side and circumferentially oriented vascular smooth muscle cells in the thicker outer layer. A two-compartment bioreactor culture chamber was designed to emulate the in vivo physiological environment of the blood flow on the scaffold’s luminal side and to maintain the two cell layers in their preferred culture media with the ultimate aim to improve their respective differentiation.

METHODS: Scaffold fabrication: A nonwoven luminal layer was created with solution electrospinning (solES) after which a second, oriented layer with big pores was deposited with melt electrowriting (MEW) (3 mm Ø, 2 cm length). Poly-ε-caprolactone (PCL) was used to create both layers. Bench-top experiment: Human Endothelial Colony Forming Cells (cb-ECFCs) and Multipotent Mesenchymal Stromal Cells (bm-MSCs) were seeded on the inside and onto the outer scaffold layer, respectively. Constructs were mounted into the custom-built culture chamber and perfused (physiological shear rate 115 s⁻¹) with EGM on the luminal side for 3 days, while the outside was maintained in vSMC differentiation medium. Analysis: The grafts were analyzed for the expression of a.o. vSM, extracellular matrix (ECM) and endothelial markers (gene expression and immuno/histochemical staining) and graft permeability by measuring the leakage of inulin (2-5 kDa) from the flow loop to the outer compartment.

RESULTS & DISCUSSION: The bi-layered tubular scaffolds promoted organization of the vSM-like cells in a circumferential and multi-layered fashion, and expressed the vSMC markers calponin, αSMA, SM22α and the ECM components (tropo)elastin and laminin subunits α4 and α5. On the luminal side, endothelialization was supported; the endothelial monolayer, positive for VE-cadherin/Von Willebrand factor/ CD31, was still present after perfusion and responded to shear stress, according to the upregulation of the stress responsive genes Krüppel-like factor 2 (Klf2), endothelial nitric oxide synthase (eNOS) and Cyclooxygenase-2 (COX-2). Inulin was retained in the perfusion loop, demonstrating the sealing capacity of the cells.

CONCLUSIONS: The feasibility was shown of combining solES and MEW to engineer bi-layered constructs, fostering the differentiation and stacking of the vSM-like cells, while also supporting endothelialization. The bioreactor system with the two media compartments allowed for perfusion of leak-free cell-seeded grafts, with the confluent endothelium responding to the imposed shear rate. The vSMC differentiation medium in the outer compartment stimulated the vSMC phenotype in the medial layer, improving the differentiation of the tissue engineered vascular grafts.
Incorporation of hair follicles into reconstructed human skin

INTRODUCTION: The hair follicle plays a critical role in thermal regulation, physical protection, dispersion of sweat and sebum, sensory and tactile functions and social interactions. Although human skin models have shown to be a promising tool for in vitro studies with the potential to replace animal testing, there is no model that includes the hair follicle. Skin models that closely represent human skin physiology and incorporate the hair follicle are required for basic research, modeling skin disease and in vitro drug testing. The aim of this study was to determine whether neopapilla spheroids, mimicking follicular papillae, can be incorporated into reconstructed human skin and to determine whether they have hair follicle-inductive potential in vitro.

METHODS: Dermal papilla cells were isolated from human hair follicles, expanded and used to reconstruct self-aggregated neopapilla spheroids. Neopapillae were incorporated into a bilayered skin substitute (reconstructed epidermis on a fibroblast-populated hydrogel) and cultured air-exposed to promote epidermal stratification.

RESULTS & DISCUSSION: Notably, neopapillae within the collagen hydrogel stimulated epidermal downgrowth resulting in engulfment of the neopapilla spheres within 10 days of air-exposed culture. Our results indicate that epidermal invagination might be a response to a local chemotactic gradient generated by underlying neopapillae, demonstrating the native behavioural characteristics of epidermal-dermal interactions in the initial stages of hair follicle morphogenesis.

CONCLUSIONS: Reconstructed human skin containing neopapillae with hair follicle-inductive properties can be constructed in vitro thus providing a promising new tool for investigating human hair follicle formation and related hair diseases in vitro.

Patterned discoidal microfilms modulate osteogenic differentiation
I.M. Bjørge¹, C.R. Correia¹, T.B. Yesil¹, J.F. Mano¹

INTRODUCTION: At its core, bone is composed of highly aligned collagen fibres. Thus, when directing the differentiation of stem cells towards the osteogenic lineage, an option is to use nano/micro-grooved substrates to control cell alignment and consequently the deposition of extracellular matrix [1]. Previous works using patterned surface topography are limited to 2D approaches, not fully mimicking the 3D in vivo environment of bone tissue. In order to bring surface patterning into a 3D context, we have developed patterned microfilms (PFs). Through a bottom-up approach, cell-PF aggregation forms 3D structures that can be injected, independently or encapsulated, through minimally invasive procedures. PFs act as cell carriers while delivering topographical cues via surface patterning.

METHODS: PFs were produced by nanoimprinting using CDs as nanopatterned templates. Polyvinyl alcohol counter-moulds of CDs were used to nanoimprint polycaprolactone microparticles at an optimised time, temperature, and load. The osteogenic potential of PFs was assessed by culturing pre-osteoblastic MC3T3-E1 cell line or human adipose-derived stem cells (hASCs) with plasma-treated PFs. Additionally, hASCs were cultured within a previously developed liquefied and multilayered encapsulation system [2,3]. Both systems were cultured up to 21 days in basal or osteogenic medium.

RESULTS & DISCUSSION: As aimed, PFs presented a marked grooved surface patterning. Cells adhered to PFs and proliferated, which was evaluated by an increase in DNA content for MC3T3-E1 cells aggregates. For hASCs cultured within liquefied capsules, both osteopontin and hydroxyapatite nodules were identified at 21 days for both basal (BAS) and osteogenic (OST) medium.

CONCLUSIONS: The ability of PFs to support cell adhesion, proliferation and differentiation was demonstrated. PFs have been shown to be interesting platforms for osteogenic differentiation and should be submitted to further tests for confirmation.

Oxygen conditioning effect on an in vitro co-culture model of tendon-to-bone interface
I. Calejo¹,², R. Costa-Almeida¹,², R.L. Reis¹,²,³, M.E. Gomes¹,²,³
Presenting Author: Isabel Calejo, isabel.calejo@i3bs.uminho.pt

INTRODUCTION: Tendon-to-bone interface comprises a heterotypic cellular niche. The native interface is hypovascular, suggesting that the junction is physiologically hypoxic. As it bridges tendon and bone, which require different oxygen concentrations, a tight coordination of different oxygen concentrations along the junction must be considered when trying to mimic and understand biological events occurring within the tissue. Herein, an optimized in vitro co-culture model of tendon-derived cells (hTDCs) and pre-osteoblasts (pre-OBs) [1] was used to study the effect of a restricted oxygen environment on cell behavior.

METHODS: Single cultures of hTDCs or pre-OBs and direct contact co-cultures (1:1 cell ratio) were maintained for 14 days in a 5% oxygen (O₂) tension (hypoxia) using three medium conditions containing different osteogenic supplementation ratios (OM, 0%, 50%, 100%). Controls were performed under normoxia. Cell proliferation and protein synthesis, alkaline phosphatase (ALP) activity and mineral deposition (alizarin red, AZ) were quantified. Gene expression of tendon-, bone and interface-related was assessed by RT-PCR.

RESULTS & DISCUSSION: Hypoxia reduced cell proliferation, independently of OM supplementation, in comparison with normoxia for all cultures (p<0.0001). An overall increase in matrix mineralization and ALP activity was observed at 14 days in co-cultures independently of OM supplementation, compared to pre-OBs alone (p<0.0001). Interestingly, oppositely to co-cultures under normoxia, increasing OM concentration in 5% O₂ led to a reduction in matrix mineralization in co-cultures (50%OM, p<0.009; 100%OM, p<0.0001). In terms of total protein synthesis, hypoxia led to an overall reduction in synthesis, particularly in hTDCs. A synergistic effect between heterotypic cellular interactions, osteogenic medium and hypoxia was observed in the transcription levels of interface-related markers in co-cultures (COMP, ACAN, co-culture D14, p<0.05; versus single cultures D14, p<0.0001)

CONCLUSIONS: Overall, 5% O₂ diminished proliferation and protein synthesis. Combining osteogenic supplementation and hypoxia reduced matrix mineralization by cells in co-culture. Nevertheless, studying the expression of specific markers, such as HIF-1 alpha will allow a better assessment of the hypoxic response of cells in both single and co-cultures, toward identifying the role of cell-cell interactions and OM on the expression of bone, tendon and interface-related markers.

¹BIOFORGE, CIBER-BBN, Edificio Lucia, Universidad de Valladolid, Paseo Belén 19, 47011, Valladolid, Spain ²technical Proteins Nanobiotechnology (TPNBT S.L.) Paseo Belén 9 A, 47011, Valladolid, Spain

INTRODUCTION: The development of new capillary networks in engineered constructs is essential for their survival and their integration with the host tissue.

METHODS: ELRs encoding different bioactivities (RGD, REDV, QK, DRIR, GTAR) have been designed, produced characterized following well-established methodologies previously described. These ELRs were further chemically functionalized to form hydrogels. These hydrogels have been in vitro and in vivo tested to assess their angiogenic potential.

RESULTS & DISCUSSION: Selectivity provided by REDV sequences demonstrate that adhesion of endothelial cells is markedly enhanced on those substrates functionalized with 75% REDV and 25% RGD [1]. The adhesion ratio of endothelial cells was significantly higher than for HFF1 cells, thus indicating a selective adhesion with respect to endothelial cells. RGD-REDV-bioactivated or unmodified ELR-hydrogels were subcutaneously implanted. While in vivo vascularization and host cell infiltration within the bioactivated gels were highly enhanced, the two processes were strongly inhibited in non-functionalized [2]. VEGF mimetic peptide (QK peptide), tethered chemically into ELR-based hydrogels and injected into a hind limb region in mice, enhances the formation of new capillaries within the constructs. The in vivo findings showed that a functional microvasculature was obtained in QK hydrogels, thus providing a pro-angiogenic environment for cell survival and tissue growth [3]. ELRs bearing sequences with different degradation rate (DRIR, GTAR) have proven that the control over the degradation rate of the scaffolds gives us an extra control over the formation of new functional capillaries [4].

CONCLUSIONS: Our study showed how angiogenesis and host integration of the engineered tissues can easily be controlled by modulating the functionalization of the hydrogel alone.

INTRODUCTION: Cell-mediated matrix contraction naturally occurs in tissue remodeling e.g. in scarring, as well as in engineered systems. These processes can be desirable (e.g. formation of hard connective tissue in a tendon or closure of a wound) or not (fibrotic reactions, hard capsule formation). We propose a fibrin-based platform for the quantification of cell-mediated biomaterial contraction; this allows to assess the efficacy of pro- or anti-fibrotic factors, but also illustrates the practical limits of artificial matrices, for which massive contraction during cell colonization is often not desirable.

METHODS: Fibrinogen and thrombin were mixed (along with human dermal fibroblasts for 3D-seeded constructs) and pipetted into indented poly(dimethylsiloxane) (PDMS) molds (final concentrations: 3.125, 6.25, 12.5 mg/mL fibrinogen, 1 U/mL thrombin, 20 mM CaCl₂, 2x10⁵ cells/mL for 3D seeding and 5,000 cells/cm² for 2D seeding). The resulting anchored constructs exposed to ±10 ng/mL TGF-β1 for 48h and cultured for additional 5 days.

RESULTS & DISCUSSION: 2D or 3D cell seeding resulted in markedly different contraction modalities; respectively, they produce elongated structures by “wrapping” gels along the contraction axis, or through a bulk reduction in volume. The contraction speed was inversely related to the gel stiffness, and increased with a typical fibrotic agent, TGF-β1. The latter significantly upregulated (p<0.01) both collagen 1 and α-smooth muscle actin (RT-qPCR), suggesting a myofibroblastic evolution parallel to increased contraction.

CONCLUSIONS: Collectively, these data demonstrate the applicability of this platform to evaluate aligned biomaterial contraction, to inform both anti-scarring treatments and the development of aligned engineered tissues.

Figure 2: (Left) Sketch of gel-PDMS substrate anchoring. Figure 3: (Right) Contraction of 3D-seeded constructs at day 0 and 7 as a function of fibrinogen concentration, ±TGF-β1.

INTRODUCTION: Graphene oxide (GO) is a two dimensional nanomaterial with promise as a biomaterial. Though biologically inert, GO is physically strong, and flexible; it comprises planar lattice of sp2 bonded carbon atoms and features varied oxygen containing functional groups, which are promising targets for chemical modification [1]. GO features increased hydrophilicity and superior reported cell attachment characteristics compared to pristine graphene and artificial polymers [2]. Graphene materials have highly desirable properties such as electrical conductivity [3], and therefore GO is of interest as a scaffold for neural tissue regeneration. Aim: To examine the compatibility of growing cells of the central nervous system with GO surfaces.

METHODS: GO was assembled into homogenous, unbroken plasticized coatings onto glass or plastic disks via spin coating. Primary neurons prepared from 3 day postnatal mice or SH-SY5Y human neuroblastoma cells were seeded on surfaces at 20,000 cells per surface. Primary neurons were subsequently maintained in Neurobasal Plus media. Differentiation of SH-SY5Y cells was induced with 3 µM retinoic acid. Live cell cultures were imaged and cells assessed for morphology and viability. Fixed cells were imaged for immunoreactivity.

RESULTS & DISCUSSION: GO surfaces facilitated cell attachment and supported typical morphology and proliferation. When induced to differentiate, SH-SY5Y cells on GO surfaces developed cholinergic phenotypes with neurite-like projections arranged as intercellular networks and remained viable for more than 14 days in vitro (>95% viability). Primary Neurons on GO surfaces developed expansive TAU positive dendritic morphologies by 25 days in vitro, and synaptophysin positive vesicles at dendritic termini, when co cultured with astrocytes. Overall, cell cultures attached to GO surfaces displayed superior morphology, maturity and viability than controls.

CONCLUSIONS: Our results indicate GO is a compatible cell-supporting and instructive substrate for neural tissue scaffolds and is suited to culture of neural tissues. Spin coating provides a robust method to prepare batches of substrates.

A new nanoindentation method for local dynamic mechanical analysis (micro-DMA) of heterogenous silicon elastomers (PDMS) and other viscoelastic biomaterials

J. Pyszkowski ¹

Presenting Author: Jakob Pyszkowski jakob.pyszkowski@optics11.com

¹Optics11, De Boelelaan 1081, 1081 HV Amsterdam, The Netherlands

INTRODUCTION: The micro-mechanical properties of biological tissue are highly diverse and play an important role in tissue engineering and regenerative medicine, by regulating a wide range of physiological processes. Local dynamic mechanical analysis of complex tissues or heterogenous polymers while immersed in liquids proves to be very difficult to perform. Based on previous experiments on PDMS using a ferrule-top indentation method, we present here our results on similar sample using a modified nanoindentation setup, the Piuma Nano-indenter, for local viscoelastic characterization.

METHODS: Silicon elastomers were prepared in a 35mm petri dish, with a Sylgard 184 ratio of 50:1 and 20:1, respectively, resulting in a mix of concentrations to create a stiffness gradient within the sample in range of stiffnesses representative for biological tissues. We demonstrate that our micromechanical testing technique can accurately determine moduli in the range between 10 and 100kPa and over a frequency range of 0.1–10 Hz. This method is featured with a fiber-optical ferrule-top micro-machined force transducer (Figure 2), enabling a wide range of mechanical tests: from quasi-static experiments to derive elastic moduli, to step-response tests (e.g. creep, stress-relaxation), dynamic mechanical analysis (micro-DMA) and constant strain rate tests to characterize sample viscoelastic behavior.

RESULTS & DISCUSSION: Dynamic nanoindentation measurements show increased storage modulus $E'$ and loss modulus $E''$, ranging from 15kPa to 89kPa, and from 1.5kPa to 78 kPa, respectively. Single measurement points of a total number of 100 were collected across a grid of 1cm x 1cm for oscillation frequencies of 0.1, 1 and 10 Hz.

CONCLUSIONS: The collected micro-DMA data on PDMS demonstrate the ability of the featured nanoindentation system to extract very localized viscoelastic properties of tissue-like materials, in agreement with macroscopic rheology measurements [2].

Figure 1: (left): Section of the measured grid showing an increase of $E'$ over a length of 4.5mm. Figure 2: (right): Ferrule-top nanoindentation probe, including a cantilever and optical fiber for force readout [2].

ACKNOWLEDGEMENTS: Financial support as well as the Piuma Nanoindenter setup was received and sponsored by Optics11, Amsterdam, NL
Optimization of 3D bioprinting of human neuroblastoma cells using sodium alginate hydrogel

J. Lewicki1, J. Bergman1, C. Kerins1, O. Hermanson1

1Department of Neuroscience, Karolinska Institutet, Biomedicum, Stockholm, Sweden

INTRODUCTION: There are many parameters in extrusion-based three-dimensional (3D) bioprinting of different materials that require fine-tuning to obtain the optimal print resolution and cell viability. To standardize this process, methods such as parameter optimization index (POI) have been introduced [1]. The POI aims at pinpointing the optimal printing speed and pressure to achieve the highest accuracy keeping theoretical shear stress low.

METHODS: 1×10⁷/ml SK-N-BE(2) human neuroblastoma cells were encapsulated in 2% sodium alginate (SA) and 3D printed using freeform reversible embedding of suspended hydrogels (FRESH) method [2] and Allevi 2 3D bioprinter. Set of four different extrusion pressures (5, 7.5, 10, 12.5 psi) and four speeds (2, 4, 6, 8 mm/s) were used for the material deposition. POI method was used to determine the optimal printing parameters based on printed line width analysis. Printed constructs were also analyzed in the context of cell viability and aggregation up to 7 days in cell culture.

RESULTS & DISCUSSION: Our results demonstrate a notable difference between optimal parameters for printing 2% SA with and without cells in the hydrogel. We also detected a significant influence of long-term cell culture on the printed constructs. When taking these conditions into consideration, we could define a set of parameters that resulted in good quality prints maintaining high neuroblastoma cell viability (83% viable cells) during 7 days of cell culture using 2% SA and FRESH bioprinting. The highest POI value was achieved for 7.5 psi extrusion pressure and 8 mm/s of deposition speed.

CONCLUSIONS: This observation suggests that the POI has to be evaluated in the perspective of the final application, including presence of cells and cell culture conditions.

ACKNOWLEDGEMENTS: This study was supported by project grants from the Swedish Research Council (VR-MH), the Swedish Cancer Society (Cancerfonden), and the Swedish Childhood Cancer Foundation (Barncancerfonden) to O.H.

INTRODUCTION: Tissue engineering strategies must seek to reproduce native cellular organization to ensure synchronous function, mechanical anisotropy and correct tissue maturation.

METHODS: We employed an acoustic patterning device with integrated piezotransducers to deliver ultrasound standing waves (<30 min, 2.0-2.1 MHz) that could pattern cells into various geometries (e.g. lines, clusters). Hydrogels were used to encapsulate the cell arrays for tissue engineering. For instance, C2C12 myoblasts patterned in lines were used to engineer aligned skeletal muscle.

RESULTS & DISCUSSION: Here we demonstrate, for the first time, that acoustic fields can be used to produce aligned cell fibers in an engineered tissue. For instance, we show that a brief application of ultrasound standing waves can be used to pattern myoblasts into collagen-based hydrogels for the engineering of muscle tissue with dense, aligned fibers. This strategy offered great flexibility across different bioengineering protocols, addressing several key limitations facing in vitro muscle tissue engineering. Myoblasts patterned in a type I collagen hydrogel contracted the surrounding matrix to produce high-density muscle fibers, anisotropic tensile mechanics and a remodeled extracellular matrix. Indeed, the cell-mediated contraction was used in combination with collagen clamping to generate, to the best of our knowledge, the first instance of a tissue construct exhibiting cell alignment on both an individual cell and population-wide level. A third protocol, utilizing photo-crosslinked GelMA hydrogels, was used to demonstrate that acoustic patterning can significantly enhance myofibrillogenensis, compared to unpatterned controls. Negligible myoblast fusion was observed in the unpatterned tissue after seven days, however, the acoustically-patterned muscle exhibited upregulated MRF4, a key marker of myotube maturation, and large, multinucleated myotubes expressing α-myosin skeletal fast and tropomyosin. The myotubes were aligned within the acoustically-patterned muscle fibers, with the patterning extending across entire tissue constructs (cf. 350 cell widths / 7 mm). We have extended this method to engineer other anisotropic soft tissues using 2D ultrasound fields to pattern stacked fibres in full 3D volumes.

CONCLUSIONS: The ability to fabricate anisotropic tissue constructs with ordering over large length scales will be a critical factor in the engineering of functional tissue grafts and physiologically-relevant disease models. Indeed, the ability to rapidly and dynamically align label-free cells en masse using generic hydrogels and cell culture apparatus makes this platform technology highly advantageous for a host of next-generation bioengineering strategies.
Development and characterization of a photo-crosslinkable hyaluronic acid bioink for neural tissue engineering applications

INTRODUCTION: Regeneration of the spinal cord after injury remains a great challenge due to the complexity of this organ. Inflammation and gliosis at the injury site hinder the outgrowth of axons and hence prevent synaptic reconnection and reinnervation of paralysed tissue. Implantable biomimetic biomaterials have proven to be an exciting tissue engineering approach to promote axon outgrowth across the injury site. Hydrogels provide a substrate for cell adhesion and migration while also reducing inflammation after injury. Hyaluronic acid (HA) is the main component of the spinal cord extracellular matrix and plays a vital role in cell proliferation and axonal guidance. In this study, we have characterised a photocrosslinkable HA-tyramine hydrogel from a chemical, mechanical, electrical, and biological perspective.

METHODS: Using Rheology, the mechanical properties of HA-tyr in response to incremental increases in UV exposure was measured and compared to that of isolated rodent spinal cord tissue. Using potentiometry, the electrical conductivity of HA-tyr was examined. Using the Nanoscribe two-photon polymerisation (2-PP) 3D printer, HA-tyr was photocrosslinked according to computer aided Design (CAD) created geometries. The laser power and scan speed was optimised to create reproducible 3D printed hydrogels. The cytocompatibility of photocrosslinking HA-tyr was assessed using dorsal root ganglion explants and immunohistological staining.

RESULTS & DISCUSSION: From our experimentation, we have examined the degree of tyramine functionalisation of HA via nuclear magnetic resonance spectroscopy. This parameter is important in determining the crosslinking efficiency of any photocrosslinkable bioink. We have found that the mechanical properties of HA-tyr can be tuned to mimic that of native spinal cord via optimization of the photo-initiator concentration and UV exposure. Using potentiometry, the electrical conductivity of photocrosslinked HA-tyr was assessed and compared to that of native spinal cord tissue at physiologically relevant voltages. Spinal cord tissue has greater conductivity which could be correlated with the isotropic structure and myelin presence. Using dorsal root ganglion explants, the tissue compatibility of photocrosslinked HA-tyr was assessed using immunohistochemistry. The laser power and scan speed of the 3D printer was optimised to facilitate hydrogel patterning.

CONCLUSIONS: This generated data clearly illustrated the feasibility of using tyramine functionalized Hyaluronic acid as a bioink for neural engineering.

Recent advances in stem cell technology have led to the development of three-dimensional (3D) culture systems, which have fueled hopes to augment the physiological relevance of high throughput screens (HTS). However, current protocols based on extracellular matrices such as matrigel either yield complex but highly heterogeneous aggregates (“organoids”). Here, we present a fully HTS-compatible workflow combining automated seeding, culture, and analysis of neural precursor cells resulting in highly homogenous automated midbrain-like neural microtissues (ANTs). The ANT display a zonal 3D architecture and mimic relevant organ function in the form of spontaneous neural activity synchronized across the entire microtissue. We explore the effects of different extracellular matrices on neural outgrowth in 3D, comparing defined and non-defined matrices. Overall, our techniques solve three main challenges that have prevented 3D cell culture from use in HTS: Intra- and inter batch variation, scale up, and automated cost-efficient single-cell readout. We utilize this standardized technology to assess the effect of extracellular matrix on neural outgrowth in 3D.
Crucial geometrical factors in engineering cell shape for controlling type I and II collagen mRNA expression of human chondrocytes

¹G.E.R.N. Tissue Replacement, Regeneration & Neogenesis, Dept. of Orthopedics and Trauma Surgery, Germany ²Dept. of General and Visceral Surgery; Albert-Ludwigs-University of Freiburg, Hugstetter Straße 55, 79106 Freiburg, Germany

INTRODUCTION: Chondrocytes (CHs) that dedifferentiate display changes in cell morphology that are associated with changes in the expression levels of type I and II collagen (COL I,II). Utilizing this association of form and function, we aimed to engineer specific CH shapes for controlling CH mRNA expression through micro-patterned adhesion sites (MPs). The goal was to identify geometric aspects of cell shape that are crucial for controlling COL I and II.

METHODS: Human primary CHs from osteo-arthritis articular cartilage were cultured on fibronectin-coated MPs for 24 h or 7 days. The customized MP geometries were H-shaped or designed as circles either with increasing area, aspect ratio (AR) or number of prongs while keeping the other parameters constant. F-actin, β-tubulin and the nuclei were IF-stained. The recorded images were used for calculating a panel of 7 quantitative shape descriptors (cell area, AR, roundness, length, width, circularity, solidity) and for generating image heatmaps. ddPCR was used to measure the mRNA expression of COL2A1 and COL1A2. Partial least square (PLS) regression was performed to identify the relative impact of MP-engineered CH shape on mRNA expression.

RESULTS & DISCUSSION: Almost all shape descriptors of CHs on MPs were significantly different from CHs on non-patterned controls (p<0.05). Comparing CHs on MPs among MPs with varying area, AR, and prongs revealed significantly different cell shapes (p<0.05), predominantly for cell area and solidity. Thus, MPs can be used for engineering CH shape but MP and cell geometries did not express a one-to-one relationship. In CHs with two nuclei, a CH AR from 1.2 to 1.5 directed the nuclei locations towards the longitudinal MP axis. This was more pronounced in CHs with a higher AR and demonstrated that nucleus distribution and, in turn, the direction of CH division can be controlled through MP AR. COL2A1 and COL1A2 mRNA expression levels of CHs on MPs were significantly different from CHs on non-patterned control areas (p<0.05). The range of fold-change in expression levels that we achieved through using MPs was 0.1-0.7 for COL1A2 and 0.4-3.9 for COL2A1, relative to non-patterned control CHs. Investigating the effects of all 7 shape descriptors on mRNA expression, PLS uncovered that COL1A2 mRNA expression was correlated highest to MP-engineered cell solidity (PLS loading coefficient: -0.467), whereas COL2A1 expression was correlated highest to cell AR (PLS loading coefficient: -0.649). Testing for significance revealed COL1A2 expression fold-change correlated significantly with cell solidity (cc: -0.796, p<0.0001) and COL2A1 correlated significantly with cell AR (cc: -0.362, p<0.05).

CONCLUSIONS: CH shape can be engineered by MPs and can be used for controlling the orientation of cell division and type I and II collagen expression modulation. The factors most crucial were cell AR and solidity.

Optimisation of microparticle formulations for cytokine delivery for macrophage modulation in spinal cord injury

J.Z. Stening¹, F.R.A.J. Rose¹, L.J. White¹
Presenting Author: Jasmine Stening, paxjzs@nottingham.ac.uk
¹Regenerative Medicine and Cellular Therapies, School of Pharmacy, University of Nottingham, UK

INTRODUCTION: Currently spinal cord injury lacks treatment capable of restoring limb function and sensation. Pharmaceutical strategies focus on alleviating the triggered high inflammatory environment. Understanding macrophage behavior and roles of their sub phenotypes has suggested a method for controlling inflammation by modulation towards a pro-immunoregulatory subgroup (M2) using cytokine IL-4. Microparticles are widely reported as drug delivery methods for controlled and sustained release. We aim to determine suitable release profiles for IL-4 delivery.

METHODS: Particles were manufactured using double emulsion [1,2] with 50:50 or 85:15 (lactide:glycolide ratio) PLGA (52kDa). Release kinetics were tailored by: (i) incorporation of a PLGA-PEG-PLGA triblock modifier (TB) [1] and (ii) changing the total polymer (TP) percentage. Total model protein (Lysozyme) loaded was 10mg/ml for 1g polymer and 5mg/ml for 500mg polymer. Release results were reported as μg protein/ mg particles with a maximum of 10μg/mg encapsulated. Protein encapsulation efficiencies and release were analysed using a micro BCA assay to detect total protein content.

RESULTS & DISCUSSION: Microparticles fabricated were 20-50μm in size and had a smooth morphology. In a comparison of surface thickness the fastest release was observed for 10%TP 85:15 PLGA with a burst release of 2.5μg/mg on day 1. The slowest release occurred for 10%TP 50:50 PLGA with 1μg/mg released by day 20. In a comparison of triblock percentages for 20%TP 50:50 PLGA, 30%TB showed the fastest release with 10μg/mg released by day 20 and 0% and 20%TB showed the slowest release. 10%TB showed a burst release of 3μg/mg at day 1 and promising sustained and continuous release to 6μg/mg.

CONCLUSIONS: Particles prepared from 10% or 15%TP were unsuitable for controlled release with a fast burst followed by minimal daily release. Particles manufactured from 50:50 and 85:15 PLGA alone displayed release too slow for IL-4 delivery. Addition of a PLGA-PEG-PLGA TB enabled release to be controlled with less initial burst release and accelerated overall release. Microparticles fabricated from 20%TP, 50:50 PLGA with 10%TB showed a release profile most suited to controlled release.

ACKNOWLEDGEMENTS: Supported by the International Foundation for Research in Paraplegia, Switzerland ‘Combining stem cell and drug delivery to modulate macrophage phenotype toward M2 in spinal cord injury’, grant no. P155.

INTRODUCTION: Over 10 million people worldwide suffer from corneal blindness with a yearly prevalence rate of 1.5 million. One important cause of corneal blindness is related to dysfunction of the corneal endothelium. This monolayer of cells maintains the cornea in a state of physiological deturgescence via a pump-and-leak mechanism. Human corneal endothelial cells cannot undergo mitosis and therefore cannot regenerate. Following ageing, trauma or disease, the cell density will drop below a critical threshold thereby impairing the efficient pumping of excessive fluid from the cornea, leading to edema. Concomitant loss of the organized collagen structure results in opacity, thereby impairing vision. Currently, the only treatment consists of transplantation of healthy cadaveric corneal tissue. Unfortunately, donor supply does not meet the demand, thereby underlining the need for tailored synthetic scaffolds to develop ex vivo manufactured biomimetic grafts.

METHODS: Transparent membranes were developed by spincoating onto glass slides (⌀ = 12 mm) using a multi-layer approach combining: a sacrificial gelatin layer, a poly(D,L-lactide) (PDLLA) layer (Corbion) for structural integrity and a UV-crosslinkable, functionalized gelatin as extracellular matrix (ECM) mimic. Different gelatin derivatives were evaluated including methacryloyl and norbornene derivatives. An Argon plasma treatment prior to gelatin deposition ensured covalent attachment of gelatin. The membranes were characterized for glucose diffusion, membrane thickness, transparency, surface composition and in vitro biocompatibility using immortalized corneal endothelial cells.

RESULTS & DISCUSSION: PDLLA was selected as starting material to provide mechanical integrity. In vitro biological assays indicated that PDLLA as such does not provide cell interactivity. Therefore, a crosslinked gelatin coating was applied. The produced membranes were transparent throughout the visual spectrum (> 98%) for thicknesses ranging from 0.8 to 1.5 µm thereby complying to the dimensions of the natural Descemet's membrane (<10 µm). Furthermore, the membranes exhibited sufficient glucose diffusion both in the presence and absence of a gelatin coating, which is an important prerequisite for membrane function. Finally, upon cell seeding, the primary corneal endothelial cells retained their characteristic hexagonal shape. Immunocytochemistry showed the expression of Na⁺/K⁺ ATPase and ZO-1, the hallmark proteins to identify healthy functional endothelial cells. Finally, the number of focal adhesion points of cells seeded onto the membranes showed no significant difference compared to the positive control.

CONCLUSIONS: Ultrathin (< 1.5 µm) membranes were constructed using PDLLA for mechanical integrity and gelatin as ECM mimic. The membranes were transparent, permeable to glucose and supported cell culture rendering them interesting towards microsurgery thereby alleviating the current donor shortage.
Collagen-hydroxyapatite nano-scaffold as a novel bone void filler

INTRODUCTION: The next generation of bone graft substitutes shall provide a handable product for an efficient bone ingrowth and regeneration causing neglectable side-effects. They should primarily demonstrate high patient safety, therapeutic efficacy, unlimited availability, but also cost efficiency. In this study, a biomimetic scaffold that mimics the natural bone tissue microenvironment based on collagen-nanoceramics has been designed.

METHODS: To produce extracellular matrix (ECM)-mimicking nano-scaffold for bone repair with preserved native collagen structure, a unique electrosprinning technology was used. By means of different techniques including SEM analysis, MTT proliferation assay, ALP (alkaline phosphatase) activity and immunocytochemistry, the spun matrices were comprehensively characterized. Mesenchymal stem cells from human adipose tissue (hASCs) have been used to characterize the developed matrices (designated as SpinFill). In addition to biocompatibility studies, the scaffolds were compared for their performance in vitro. For the comparison, two similar products already existing on the market were used as reference devices (Cerasorb Foam and Vitoss Scaffold Foam). To assess adhesion and proliferation, the colorimetric raw data (OD-values) of the respective MTT-assay normalized to product volume were used in order to compare the analyzed products. The osteogenic potential of the different products was compared using normalized ALP-values. The finding was confirmed by immunocytochemical staining for osteogenesis marker osteopontin (OPN, Fig. 1D).

RESULTS & DISCUSSION: SpinPlant technology relies on the preservation of the collagen nativity, assuring stability of the product, which is a prerequisite for an efficient osseointegration and new bone formation. SpinFill consists of biomaterials shown to be non-toxic, biodegradable and at the same time stable and porous, promoting cell adhesion and spreading. The in-vitro performance of SpinFill was in several aspects significantly better than that of both reference devices.

CONCLUSIONS: These findings collectively support the therapeutic potential of SpinPlant’s biodegradable collagen-hydroxyapatite nano-scaffold for bone regeneration.

Figure 1: Macroscopic (A) and microscopic (B- 100x, C-50,000x) view of the collagen-hydroxyapatite nano-scaffold, when seeded with human ASCs showed prominent staining for F-actin (red) and osteogenesis marker osteopontin (green, OPN in D), two weeks after differentiation in vitro. SEM image reveals a complex organization of the nano-scaffold (C).
Long term fate of iron oxide nanoparticles in the organism
J. Volatron¹, G. Charron¹, M. Tharaud², F. Gazeau¹

¹Matière et Systèmes Complexes (MSC), Paris Diderot University, Paris, France ²Institut de Physique du Globe de Paris (IPGP), Paris, France

INTRODUCTION: Iron oxide nanoparticles (IONPs) are of particular interest in tissue engineering, regenerative medicine and cancer therapy due to unique magnetic properties allowing MRI monitoring, magnetic stimulation of cells and local hyperthermia tissues [1]. In this context the evaluation of IONPs life cycle is a major challenge, to optimize upstream their properties and develop nano-object that are robust and safe to use. Our group have previously shown that IONPs injected intravenously in mice underwent local degradation within lysosomes of macrophages in spleen and liver [2] with local iron recycling by endogenous protein [3]. Here we propose a multi-scale approach to follow the six months’ fate of all the constituents of the IONPs: the magnetic core, the coating (ensuring their stability) and the non-magnetic byproducts (resulting from the degradation of the magnetic core).

METHODS: At the organism scale, the main difficulty is to distinguish the exogenous elements (intravenously injected IONPs and their byproducts) from endogenous iron. Our strategy was thus to enrich the inorganic core of IONPs with a minor iron isotope, ⁵⁷Fe, and to double-label the coating with two lanthanides. IONPs were followed-up by MRI, Transmission Electron Microscopy (TEM) and their magnetic properties were quantified by Ferromagnetic Resonance (FMR). Their byproducts (nonmagnetic ⁵⁷Fe species) and the lanthanide coating were quantified by High resolution ICP-MS. The fate of these labelled IONPs were follow up in the mice over a period of 6 months.

RESULTS & DISCUSSION: Surprisingly, during the first hour after intravenous injection, there is a partial dissociation of the coating from IONPs. The coating is then directed to the kidneys and eliminated from the body. One hour after injection, IONPs are mostly located in liver and spleen. Rapid and complete degradation is observed in liver during the first month after injection, while the degradation is slower in spleen. Finally, from three months after injection, we observed a transfer of the non-magnetic byproducts from liver to the spleen via red blood cells, testifying the recycling of exogenous iron by the organism.

CONCLUSIONS: These data illustrate the fate, the remediation and the recycling of exogenous IONPs in the organism over a period of six months.

INTRODUCTION: Bioactive glass (BG) is known for its ability to bond to soft and hard tissues and form hydroxyapatite via ion exchange. BG ions have been shown to upregulate osteogenic differentiation of mesenchymal stem cells. Here, ability of Silica and Calcium ions released from BG cotton wool-like fibres to enhance osteogenesis and true apatite formation as early as day 4, when compared to standard procedures, is showcased.

METHODS: Bioactive glass (BG) with composition 70% SiO and 30% CaO was prepared through sol-gel process and electrospun into fibres. Conditioned medium (BGCM) was prepared by incubating 5 mg of fibres per 1 ml of neat media for 24 h at 37 °C. Final ionic concentration was measured through Inductive Coupled Plasma (ICP) spectroscopy. Human bone marrow MSCs were cultured with osteogenic differentiation media (Promocell) alone or enriched with bone morphogenic protein 2 or BGCM. To evaluate osteogenic differentiation and mineral deposition alkaline phosphatase (ALP) enzymatic activity, collagen type 1, osteocalcin, calcium (alizarin red) and collagen deposition (Sirius red) were investigated. Gene expression profile was assessed using the Human Osteogenesis RT² Profiler™ PCR Array. SEM, EDX and XRD mapping was performed to evaluate and characterize the bone apatite formation.

RESULTS & DISCUSSION: BGCM supplemented osteogenic media stimulated significant calcium phosphate deposition, as verified by EDX. Alizarin red staining demonstrated significant (p<0.005) calcium deposition in BGCM supplemented osteogenic media as early as day 4. A sharp increase of ALPase enzymatic activity at day 4 and decline afterwards was also observed indicating an early onset of osteogenic differentiation of MSCs. EDX and XRD map have confirmed that the produced deposits are made of calcium and phosphorus. Effect on osteoclasts will also be presented.

CONCLUSIONS: Our data demonstrate the impact of inorganic ions on osteogenic differentiation of MSCs. This could potentially be used alongside standard osteoporosis treatment to enhance localized bone formation.

Figure 1: Alizarin red staining of MSCs after 7 days in culture with Osteogenic media (left) or osteogenic media enriched with BG ions (right). Red indicates calcium phosphate deposits. Scalebar-500 µm.

INTRODUCTION: The formation of a vascular network in a tissue engineered construct in vitro remains an open problem [1]. Acoustic radiation forces are gaining attention as an attractive method of quickly patterning microparticles, including cells, within a support medium, with little to no cellular damage [2, 3]. Here, we introduce a proof-of-concept design for a modular ultrasonic patterning system, capable of rapidly patterning cell-scale aqueous droplets.

METHODS: Arrays of ultrasonic transducers operating at a frequency of 40 kHz were positioned in 3D printed PLA supports, following computational modelling of predicted acoustic pressure fields. Medical nebulisers (Healthcare World) and a piezoelectrically-actuated droplet-on-demand (DOD) generator (Microfab), were used to produce droplets of 1–5 µm and 80 µm, respectively. Watersensitive paper (Syngenta), which turns blue upon contact with aqueous solutions, was used to visualise deposition patterns. Alginate microbeads were formed by depositing a 0.5% aqueous sodium alginate solution via the DOD generator into a bath containing 102 mM CaCl₂.

RESULTS & DISCUSSION: Water droplets produced by a medical nebuliser (< 5 µm diameter) and DOD generator (80 µm) were patterned within seconds of exposure to the acoustic field, as were the larger calcium alginate microbreads. Spatial resolution is determined by a combination of the initial droplet size distribution and the ultrasonic standing wave pattern. Droplet drying kinetics indicate a significant reduction in droplet radius over time, dependent upon polymer concentration and ambient humidity, with effective polymer concentration increasing over the drying period. These findings indicate that droplets can initially be larger and more dilute than the desired final size and concentration.

CONCLUSIONS: The patterning we demonstrate forms a first step towards the generation of larger, high-resolution 3D structures, including vasculature. Crucially, the resolution of this technique has the potential to approach cellular length scales.

INTRODUCTION: Current challenge in 3D printing in biological fields lie in lack of proper printing materials. Therefore, development of hydrogel materials to enable successful structured printing of biological substitute is on high demand. Our study aimed to formulate a hydrogel complex having proper rheological, chemical and biological properties to be useful for printing tissue scaffolds, especially for skin tissue regeneration. We characterized the complex formulation in vitro and in vivo for its potential for enhanced skin regeneration.

METHODS: 1. Hydrogel printing: The gelatin based hydrogel complex was structured by printing under 40 % fill density, 250 % input flow and 5 mm/s print speed. The temperature of dispenser and bed were 20 °C and 15 °C respectively. After printing, UV light was irradiated for 4 minutes. 2. Biocompatibility study: C₂C₁₂ and 3T3 cells (1*10⁶/ml) were respectively mixed with hydrogel complex before it print. Mixed cell and hydrogel complex were printed on chamber slide. Live/Dead assays were conducted at day1, day3, day5 and day7. 4. Structural Stability : (L₂-L₁) / L₁ where L₁: Length of 3D printed nose with day 0 / L₂ : Length of 3D printed nose after immersion. Structured hydrogel was immersed in PBS for 21 days. 5. Water absorbency: (W₂-W₁) / W₁ where W₁ : Weight of 3D printed hydrogel before immersing / W₂ : Weight of hydrogel after swelling. 6. Mechanical properties: Universal Test Machine (OTT-003, Oriental TM, South Korea), Tested with 3 kgf load cell and 30 mm gauge length. 7. In vivo study: Safety and efficacy were investigated with mice for 4 weeks.

CONCLUSIONS: The newly hydrogel complex has a great potential as a material for patterning 3D structure for soft tissue reconstruction since they are easy to print, gelling, not toxic, stable, and cost effective.

INTRODUCTION: Intervertebral disc (IVD) degeneration is the most common cause of specific low back pain [1]. To treat the IVD degeneration, human nasal chondrocytes (hNCs) were identified as a possible alternative cell source due to their ability to survive and produce extracellular matrix in an IVD environment. hNCs were shown to possess high proliferation capacity and are capable to adapt to heterotopic transplantation sites [2]. This study aims to investigate the interaction of hNCs with human nucleus pulposus cells (hNPs) in a 3D in vitro co-culture model.

METHODS: In vitro nucleus pulposus micro-tissue was fabricated by pooling eight hNPs micro-aggregates (25’000 cells per micro-aggregate, cultured for two weeks) together. GFP-labelled hNCs were then added to the hNP micro-tissue either as single cell suspension (200’000 cells per micro-tissue) or as 16 micro-aggregates (12’500 per micro-aggregate, cultured for two days). Monoculture hNPs and co-culture hNPs-hNCs were cultivated for two weeks. Preliminary analysis was conducted upon macroscopic investigations during co-culture time.

RESULTS & DISCUSSION: Macroscopic investigations showed that: (i) control hNPs micro-aggregates in monoculture did not fuse into a stable construct, (ii) hNPs micro-aggregates in co-culture with hNCs suspension or with hNCs micro-aggregates merged to create one accumulative mass (indicating positive interactions between the two cell types), (iii) metabolic activities was high and similar in the two co-culture groups (indicating new matrix formation).

CONCLUSIONS: Preliminary results indicate that the experimental approach to investigate the interaction of hNCs with hNPs is feasible. Visual evaluation suggests that co-culture of hNCs and hNPs has an advantageous effect on matrix production. Histological and biochemical analysis will be performed to validate and quantify the impact of hNC cells on the viability, proliferation and extracellular matrix production of hNPs and vis-versa.

INTRODUCTION: Without a functional vascular network, large engineered tissues will ultimately fail. The overall aim of this study is to 3D bioprint a prevascularised construct and to investigate its capacity for bone regeneration. The first aim of this study was to compare different bioink formulations, cell combinations and culture periods for their potential to establish stable microvessels both in vitro and in vivo. The second aim of this study was to incorporate vessel forming bioinks into a 3D bioprinted cartilage template and to investigate the capacity of this construct to support endochondral bone formation in vivo.

METHODS: In vitro vessel study: Three bioink hydrogels (alginate, GelMA and fibrin) were seeded with human umbilical vein endothelial cells (HUVECs) cultured in EGM-2 media with 5ng/mL of VEGF for 10 days in vitro. Groups were evaluated for average vessel length using ImageJ. In vivo vessel study: Bioprinted fibrin constructs containing MSCs, HUVECs or HUVECs & MSCs were cultured for either 12h or 7 days in EGM-2 with VEGF and subcutaneously implanted into balb/c mice for 1 & 2 weeks. Constructs were evaluated for vessel number using histology (H&E). In vivo Bone formation: Cartilage templates were engineered by bioprinting fibrin laden with MSCs (10E6 cells/ml) with or without an inner channel. Constructs were cultured in chondrogenic media for 2 weeks at 5% O₂ and a further 1 week at 20% O₂. At this point, using the fibrin bioink a co-culture of HUVECs:MSCs was 3D printed into the inner channel of one the groups, creating 3 distinct bioprinted cartilage templates: Solid, Empty channel & Vasco channel. All groups were cultured in EGM-2 media with 5ng/mL of VEGF for 7 days and implanted subcutaneously into balb/c mice for 4 & 8 weeks. Bone formation was determined by µCT analysis.

RESULTS & DISCUSSION: In vitro vessel analysis: Over the course of 7 days, HUVECs had formed microvessels in both GelMA and fibrin, however there was no endothelial sprouting observed in the Alginate. Fibrin bioinks supported the most consistent growth of microvessels over time. From this point on Fibrin was chosen as the optimum bioink for all future studies. In vivo vessel analysis: At day 7, only the cultured co-culture constructs (containing an in vitro engineered vasculature) contained perfused vessels. This beneficial difference was maintained over 14 days in vivo. In vivo Bone Analysis: All bioprinted cartilage templates supported robust endochondral bone formation in vivo. Although prevascularizing constructs lead to a higher percentage of area vascularized within the engineered tissue, implant architecture appeared to play a more dominant role in determining the levels of mineralization in vivo compared to prevascularizing the tissue prior to implantation.

CONCLUSIONS: These results show that fibrin is an ideal bioink to support HUVEC sprouting and microvessel formation. Bioinks of fibrin containing a HUVEC:MSC co-culture support the development of a stable primitive vascular network in vitro. Furthermore, prevascularizing 3D printed constructs in vitro using this novel bioink led to increased anastomosis when implanted in vivo. Future studies will investigate if incorporating microvessels into 3D bioprinted templates will lead to enhanced bone regeneration in large bone defects.

INTRODUCTION: Lactate plays key roles in multiple cellular processes, including angiogenesis, wound healing and cancer growth and metastasis [1,2]. Herein we explored the potential role of lactate on cardiac regeneration and iPSC differentiation.

METHODS: Neonatal mice cardiac cells were isolated and incubated with L-lactate solution. Whole neonatal mice hearts were also maintained ex vivo in Matrigel and cultured with or without lactate. Human iPSCs were differentiated to cardiomyocytes by GSK3 and Wnt inhibition. Immunostaining, FACS, RT-qPCR and TEM analysis were conducted.

RESULTS & DISCUSSION: Immunostaining analysis with ki67 revealed an increase in the number of proliferating mice cardiomyocytes in the presence of lactate after 4 days of treatment. Moreover, transcription factor p63, which is involved in stem and progenitor cell regulation, was highly overexpressed in the presence of lactate, as RT-qPCR data revealed. Ex vivo culture of neonatal mice hearts showed a better maintenance of the integrity of the heart tissue up to 8 days in lactate, as well as an enhanced beating ability compared to control without lactate. This result was correlated with higher sarcomere width in cardiac tissue from hearts incubated in lactate, as confirmed by TEM image analysis. Therefore, the effect of lactate on human iPSCs-derived cardiomyocytes was also evaluated. MTS assay was used to assess the viability of these cells in the presence of different concentrations of lactate. Immunofluorescence imaging revealed the localization of p63 protein associated to the cellular membrane and cytoplasm. No significant DNA damage was observed on iPSCs-derived cardiomyocytes after incubation with lactate, as it was shown by FACS analysis on γH2A.X. Additionally, both proliferation and dedifferentiation markers were evaluated by FACS and RT-qPCR analysis.

CONCLUSIONS: Together, these data supports the use of lactate as a modulating signal for cardiac tissue engineering.

INTRODUCTION: Periodontitis is chronic inflammation of the periodontal tissues, caused by microbial pathogens in the periodontal pocket. It is the major cause of tooth loss in adult humans. The disease is treated by scaling and root planing. However, this process is not efficient enough to produce a contamination free environment, thus adjunctive therapies are often included, e.g. local administration of antimicrobials. The antimicrobials can be delivered inside the periodontal pocket via chips, gels or microspheres. However, those passive delivery methods cannot ensure the drugs to reach the inflamed spots. Therefore, an active delivery method is advantageous for the periodontal treatment. At the site of infection, reactive oxygen species (ROS) are generated by immune cells, such as macrophages, to kill the pathogens. H2O2 is the precursor for the production of most ROS and is therefore found at increased levels in inflamed tissues. The aim of this study was to develop enzyme-grafted PLGA microspheres, which can move towards high gradients of H2O2 for the treatment of periodontitis.

METHODS: The enzyme grafted PLGA microspheres were prepared by electrospraying process followed by a 1-Ethyl-3-(3-dimethylaminopropyl)-carbodiimide coupling modification. The morphology and compositions of PLGA microspheres before and after functionalization were detected by scanning electron microscope (SEM) and energy dispersive spectroscopy (EDS). Release profile of doxycycline, the incorporated drug in the microspheres was determined by high-performance liquid chromatography with ultraviolet detection (HPLC-UV) analysis. A cell model (Raw 264.7) were used to track the movement of PLGA microspheres.

RESULTS & DISCUSSION: The SEM micrographs before and after functionalized with catalase were shown in Figure 1. After functionalization, the asymmetry structure of catalase was built on the surface of PLGA microspheres. The EDS results displayed the element of Nitrogen on the functionalised microspheres, indicating the presence of catalase. The drug release profiles showed the identical patterns for the PLGA microspheres before and after functionalization, suggesting that the functionalization process did not affect drug release. The microsphere tracking experiment showed that the enzyme-grafted PLGA microspheres were sensitive to the gradient of H2O2 produced by Raw 264.7.

CONCLUSIONS: The enzyme-grafted PLGA microspheres perform a directional movement in response to the gradient of H2O2. The functionalization process did not affect the drug release from the PLGA microspheres. The developed delivery system is promising for periodontal treatment.

INTRODUCTION: 3D bioprinting of cell-laden scaffolds becomes more prevalent in bone tissue engineering for applications in personalized medicine. However, existing hydrogel-based bioinks often result in insufficient mechanical strength and poor scaffold fidelity because of swelling or shrinking [1]. Here, we incorporated a 2D nanomaterial, graphene oxide (GO), into an alginate/gelatin bioink system for improving printability and scaffold performance. The influence of GO on cell viability, cell proliferation, osteogenic differentiation and mineral formation was investigated.

METHODS: Four different GO concentrations (0, 0.5, 1, 2 mg/ml) were prepared by adding different amounts of GO in glycerol/PBS (9.1% v/v) solution. The same amount of alginate (0.8% w/v) and gelatin (4.1% w/v) was dissolved in the solution to prepare GO composite inks. Shear-thinning behavior of all inks was characterized rheometrically. Bioinks were prepared by mixing ink solution with human mesenchymal stem cells at a concentration of 5 million cells/ml. 3D cell-laden scaffolds were bioprinted layer-by-layer using an INKREDIBLE+ cell bioprinter. Scaffold morphology, mechanical properties, cell viability and cell morphology were investigated at day 1, day 7 and day 42 of cell culture in osteogenic media. Moreover, mineral formation of the 3D bioprinted cell-laden bone scaffolds was assessed by weekly micro-CT scans.

RESULTS & DISCUSSION: The GO ink solutions had higher viscosity and improved shear-thinning properties with increasing GO content. Higher compressive moduli were obtained at day 1 with higher GO concentrations. Meanwhile, scaffolds with higher GO showed improved scaffold morphology with less shrinkage and higher level of cell viability at day 1 and day 7 as compared to the lower GO and no GO groups. At day 42, 2 mg/ml GO group exhibited the lowest compressive modulus due to swelling; 1 mg/ml GO group had the best scaffold morphology with similar compressive modulus in comparison with the 0.5 and 0 mg/ml GO groups. The highest mineral volume was found in the 1 mg/ml GO group (95.56 ± 5.5 mm³), which was significantly higher than 0 mg/ml GO. Cell morphology exhibited a remarkable difference between no GO and GO groups at day 42.

CONCLUSIONS: We have demonstrated that the incorporation of GO significantly improved printability, scaffold morphology and mechanical properties while keeping excellent cell viability and cell spreading morphology. An optimal GO concentration at 1 mg/ml had the highest mineral formation at day 42.

INTRODUCTION: The complex interfacial tissue regeneration between soft and hard tissues is one of the most challenging fields in tissue engineering. Herein, we developed a model for an osteochondral scaffold consisted of bio-silicified organic-inorganic composite with mechanical and biochemical gradients for tissue reconstruction at interface between bone and cartilage. Furthermore, its functionalities can be improved through encapsulation of cells or growth factors related to osteochondral tissue repair.

METHODS: Mussel adhesive protein (MAP) was modified with silica-precipitating peptide to fabricate organic-inorganic composite. The modified MAP proteins were mixed with polycaprolactone (PLC; Sigma Aldrich) at various proportions to improve its mechanical properties. The scaffolds were fabricated by electrospinning of the mixtures. The nanofibers of the each mixture were stacked layer-by-layer to form gradient scaffolds. As the scaffolds were treated with 1 M tetramethy orthosilicate (TMOS), biosilica was rapidly precipitated within 5 min.

RESULTS & DISCUSSION: The nanofibers were successfully fabricated from each mixture of the modified MAP and PCL by electrospinning (Figure 1). Each layer has different properties including biodegradability and mechanical strength depending on the proportion of constituent. It indicates that the scaffold with mechanical and biochemical gradients can be manufactured owing to superior adhesive property of MAP. Additionally, it can be developed into organic-inorganic hybrid composite via bio-inspired reaction under ambient condition.

CONCLUSIONS: It was shown that hybrid composite scaffolds with gradients can be successfully fabricated. The model for interfacial tissue reconstruction will be completed through collaboration with cells or growth factors.

Figure 1: SEM images of the mixture of the modified MAP and PCL with various ratios; (a) 1:9, (b) 2:8, (c) 3:7, (d) 5:5.

A hybrid injectable hydrogel from hyperbranched PEG macromer as a stem cell delivery and retention platform for diabetic wound healing
Q. Xu¹, Jing Lyu¹, W. Wang¹
Presenting Author: Jing Lyu, jing.lyu@ucdconnect.ie
Charles Institute of Dermatology, School of Medicine, University College Dublin, Ireland

INTRODUCTION: The injectable hydrogel with desirable biocompatibility and tunable properties can improve the efficacy of stem cell-based therapy [1-2] However, the development of injectable hydrogel remains a great challenge due to the restriction of crosslinking efficiency, mechanical properties, and potential toxicity. Herein, we generated an in situ formed injectable hydrogel system fabricated by biocompatible reagents for effective stem cell retention and delivery for diabetic wound healing.

METHODS: The new HP-PEGs were synthesized via in situ reversible addition fragmentation chain transfer (RAFT) polymerization using an FDA approved anti-alcoholic drug-Disulfiram (DS) as the RAFT agent precursor. Functionalised hyaluronic acid (HA-SH) was used to crosslink with HP-PEG to form injectable hydrogels. Mechanical strength was tested by rheometer and degradation profile were tested in PBS. Adipose-derived stem cells were encapsulated in the hydrogel to detect the cytocompatibility and stemness. In in vivo study, humanized diabetic wounds in rats were generated and treated by hydrogel, hydrogel with ADSCs. Histological assay was used to analyse the wound healing efficacy, inflammation, angiogenesis, and re-epithelialisation.

RESULTS & DISCUSSION: The in situ RAFT polymerization of PEGDA using DS as a RAFT agent precursor endows the resultant hyperbranched PEG polymers good biocompatibility and abundant pendent acrylate groups, which can be utilized to form an injectable hydrogel with a rapid gelation rate (less than 2 min) and a tunable mechanical property. The HP-PEG/HA-SH hydrogels also demonstrated non-swelling and antifouling properties. Both in vitro and in vivo biocompatibility tests showed non-toxicity of the hydrogels. ADSCs encapsulated in the hydrogels also demonstrated the maintenance of the multi-potency and secretion capacity. Hydrogel/ADSCs also exhibited accelerated diabetic wound healing and improved wound environment in a humanized diabetic wound model in rats, such as faster wound closure rate, reduced inflammation response, promoted vascularization and angiogenesis and re-epithelialisation.

CONCLUSIONS: This versatile hydrogel system encapsulated with ADSCs exhibited an accelerated diabetic wound healing process through inhibiting inflammation, promoting angiogenesis and re-epithelialization.

INTRODUCTION: Mesenchymal stromal cells (MSCs) change their phenotype in response to the environment using complex mechanosensitive signal transduction chains. Environmental signals from the ECM are translated to the nucleus through focal adhesions and the dynamic cytoskeletal modifications. Lamin A/C forms a protein meshwork under the nuclear membrane and plays a key role in transducing mechanical signals from the cytoskeleton to gene regulatory machinery in the nucleus. However, the regulation of lamin A/C expression and its role in cells’ ability to respond to a 3D environment is not well known.

METHODS: Human bone marrow-derived mesenchymal stromal cells (hMSC) were seeded on additive manufactured- and electrospun scaffolds and compared to a flat film of the same material. Lamin A/C, focal adhesion proteins and F-actin were investigated using western blot and immunofluorescent imaging. Knock downs of zyxin, lamin A/C, paxillin and YAP1 and lamin A/C overexpression were performed to study the role of these proteins in cells in a 3D environment.

RESULTS & DISCUSSION: In 2D, hMSCs form thick actin stress-fibers and focal adhesions. We have shown that in a 3D environment, additive manufactured or electrospun scaffolds, focal adhesions are few and faint and no actin stress fibers are formed (Figure 1A). Together with this, we observed a strong decrease of lamin A/C expression in both 3D environments. This change was functional, as the lower lamin A/C expression lead to improved migration through small pores, due to a more flexible nucleus. Cell density influenced focal adhesion and lamin A/C expression, but this did not account for the observed differences between 2D and 3D cell culture systems. Knock down of Zyxin abolished the focal adhesions and the actin stress fibers, and also the Lamin A/C expression. Similar to Zyxin knock down, Lamin A/C changed the actin cytoskeleton, where it only polymerized in the cell perimeter (Figure 1B). Combinations of lamin A/C overexpression and zyxin knockdown, and overexpression of lamin A/C in scaffold cultures revealed an interplay between zyxin and lamin A/C that shaped the actin network in 3D.

CONCLUSIONS: Zyxin and lamin A/C work together to regulate the actin network in 2D and in 3D constructs, dictating cell shape and phenotype. This data can be used to better understand mechanosensitive signaling and cell behavior in a 3D environment and potentially advance regenerative medicine approaches using 3D constructs.

¹Regenerative Medicine Institute (REMEDI), National University of Ireland Galway (NUI Galway), Galway, Ireland

INTRODUCTION: Translation of MSC therapies to the clinic has been slower than anticipated with mixed clinical outcomes reported. One considerable barrier to progress in the field is a lack of standardised and validated testing protocols for quality assurance leading to cell products of uncertain quality. Although minimal criteria have been proposed [1], it is apparent that these are insufficient predictors of clinical efficacy.

METHODS: Human bone marrow derived MSCs from two donors were cultured using three specified expansion conditions. The surface immunophenotype of each cell preparation were probed by high throughput flow cytometry using a combinatorial antibody profiling tool comprising of 230 antibodies.

RESULTS & DISCUSSION: Analysis of expression of the surface proteins revealed significant variation in response to culture conditions and considerably less variation between donors. Of the panel of 230 markers 107 were negative, 24 had high expression in all samples, 1 had low expression and 98 displayed significant differences between cell preparations, of which 78 were culture condition dependent. Cluster analyses revealed that marker expression in one culture condition varied considerably from the other two. Phenotypic characterization of the cell preparations, assessed by morphology and growth kinetics, showed similar patterns of variability between the culture conditions. Statistical and pathway analysis revealed a panel of markers which were highly differentially expressed between the culture conditions and could be used as indicators of cell quality.

CONCLUSIONS: These data reveal a panel of MSC markers which may be used as phenotypic indicators for enhanced in-process and product release quality testing in MSC manufacturing. Ongoing work involves the complete validation of these markers and correlation of their expression to functional attributes including angiogenic, immunosuppressive and immune modulatory capacities, differentiation and colony forming propensity.

INTRODUCTION: Low back pain (LBP), for which existing therapies are inadequate, affects over 70% of the world population, having a tremendous social and economic impact due to the enormous costs associated to treatment and work absenteeism. The years lived with this disability rank in front of those from AIDS and lung cancer among others. LBP is often caused by intervertebral disc (IVD) degeneration, which occurs with age and is accompanied by extracellular matrix (ECM) depletion [1]. As so, novel therapeutic solutions that modulate the disc microenvironment need to be developed. We have recently demonstrated the ECM changes that occur in the IVD with development and ageing, and reported that pro-regenerative molecules like COLXII and COLXIV, are almost exclusively expressed at this developmental stage [2]. As so, we propose revolutionary strategies to treat IVD degeneration by recreate a microenvironment similar to pre-natal stages.

METHODS: On one hand we have tested different solutions and treatment times for fetal NP decellularization. Decellularized NPs were assessed to evaluate biochemical, structural histological and biomechanical properties. Repopulation of the scaffolds with adult NP cells in also understudy. The acellular materials were also used to develop a hydrogel by varying pH and temperature, among others. ECM-based hydrogels were characterized by SEM and gelation kinetics. On the other hand, we have established a lentiviral system for CRISPR-mediated activation of fetal ECM genes.

RESULTS & DISCUSSION: We have identified an SDS-based protocol that is effective at removing cells from different aged NPs while preserving glycosaminoglycans and collagen content. Topographical and biomechanical analysis have shown differences among the different biomaterials which consequently impacted on NP cell phenotype. Using the CRISPR system, we were able to transduce and select clonal MSC populations homogeneously expressing the target genes and corresponding proteins.

CONCLUSIONS: This original study will provide the foundations for the establishment of a pioneer treatment based on cutting edge technology with potential to improve the already promising stem cell based therapies.

INTRODUCTION: Biomaterials have been used in the development of medical implants for several decades. Polydioxanone (PDO) is a biodegradable synthetic polymer used in the manufacturing of commonly used medical implants, namely PDS™ II suture (Ethicon Inc.). However, no review has yet been performed assessing the effect of PDO implants on safety and performance in patients.

METHODS: Authors performed a search for commercially approved PDO implants in FDA’s databases and also a literature search for their use in clinical trials or in clinic. Safety and performance was assessed based on a scoring system developed by authors and included surgical site infection (SSI) rates, inflammatory reaction rates, foreign body response and postoperative pain and fever rates. Clinical outcomes of PDO implants were also compared to clinical outcomes of implants manufactured with different materials.

RESULTS & DISCUSSION: A number of 43 PDO implants were approved by the FDA since 1981, with different shapes and sizes. In the last decade, FDA reported 1278 adverse reactions or product malfunctions and 16 recalls were found. The literature search revealed 46 publications involving the use of PDO implants in patients, covering different medical specialties. PDO sutures and meshes/plates presented low rates of SSI, inflammatory reaction, foreign body response and postoperative fever whereas PDO clips/staples showed high rates of SSI, postoperative pain and fever, with reports of failure in function. As a result, PDO clips/staples were scored low for safety and performance. The remaining types of PDO implants (sutures, plates/meshes and screws/pins) resulted in a high score for safety and performance. Results also showed that, when comparing PDO implants with non PDO alternatives, PDO sutures performed better than non PDO sutures, with higher safety score. Additionally, PDO plates/meshes and PDO screws/pins have the same performance levels as non PDO implants.

CONCLUSIONS: This review suggests that PDO medical devices are generally safe and perform well upon implantation in patients. However, it remains important to design future PDO implants (namely weight, shape, structure, and mechanical properties) with careful consideration of the host tissue properties.

Figure 1: Safety and performance of PDO implants according to type of implant. n=number of publications.

INTRODUCTION:
A novel enzymatically crosslinkable silk fibroin (SF) bioink has been developed for printing high-resolution reproducible 3D structures [1]. The potentiality/versatility of SF bioinks to be combined with different biomolecules for better mimicking native tissues has been recently investigated by introducing elastin for replicating the outer intervertebral disc [2]. In this work, the effect of elastin on the angiogenic response of SF bioprinted scaffolds was explored by using the chick chorioallantoic membrane (CAM) assay [3].

METHODS:
The 16 wt% silk fibroin (SF) and silk fibroin/elastin (S/E) (ratio of 90:10, respectively) bioprinted scaffolds were cut into 4 mm diameter cylindrical discs and implanted on CAM at day 10 of embryonic development. Filter paper (FP) and gelatin sponge (GSp) discs were used as positive and negative controls, respectively. At day 14, the excised sections were prepared for histology after acquisition of in ovo and ex ovo stereomicrophotographs. The angiogenic response was characterized by quantification of blood vessels convergence, H&E staining and immunohistochemistry for SNA-lectin.

RESULTS & DISCUSSION:
The analysis of blood vessels convergence suggests that both SF and S/E scaffolds stimulated an angiogenic response as supported by the significantly higher number of blood vessels converging to the implanted scaffolds, when compared to GSp. A small increase on the number of blood vessels converging towards the S/E scaffolds was noticed, which may result from the incorporation of elastin on SF bioink. The histological characterization has shown endothelial cells infiltration and a massive CAM tissue infiltration/ingrowth through the porous structure of both SF and S/E scaffolds.

CONCLUSIONS:
The data presented herein suggests that the presence of elastin has a positive effect on the angiogenic performance of the bioprinted scaffolds. Further studies are needed to confirm this effect.

INTRODUCTION: Type 1 diabetes arises due to destruction of insulin-producing beta cells in pancreas. Transplantation of pancreatic islets is performed as one of the treatment strategies. High post-transplantation loss of the islets motivated development of various encapsulation procedures. However, the ability of the islets to secrete insulin is impaired by lack of sufficient supply of oxygen and nutrients by dense vasculature network [1]. Biofabrication of islets-laden constructs together with a dense vasculature network might enhance islets functionality. The aim of this work was to develop bioinks for simultaneous extrusion-based bioprinting of pancreatic islets and blood vessels.

METHODS: Bioprinting of alginate blended with fibrinogen (AlgFib; Alg 4 wt/v %, Fib 5 w/v%) and alginate blended with pancreatic extracellular matrix (AlgECM; 3 w/v% alginate, 15 wt/v % ECM) bioinks was performed using Bioplotter (EnvisionTEC) equipped with a coaxial needle and microfluidic pumps after optimization of the printing parameters using CaCl₂ as a primary crosslinking agent. The as made 3D hydrogel scaffolds were crosslinked with thrombin or/and SrCl₂ and characterized with respect to shape fidelity, swelling and stability in physiological conditions. Human umbilical vein cells (HUVEC) with or without addition of human mesenchymal stem cells (HMSC) were encapsulated in AlgFib bioink and porcine pancreatic islets in the AlgECM bioink. Viability was investigated after printing and during in vitro culture by means of live/dead assay. Islet functionality was assessed using GSIS assay.

RESULTS & DISCUSSION: The bioprinting did not affect islets viability but reduced HUVEC and HMSC viability to approximately 80%. During culture, the HUVEC spread on the surface of the fibers and created dense layer of cells. Moreover, we observed proliferation of the HUVEC/MSC in the AlgFib scaffolds crosslinked only with thrombin (less stable than the AlgFib scaffolds crosslinked with thrombin and SrCl₂). The islets sustained their functionality; moreover, it was higher than in the case of free floating islets.

CONCLUSIONS: Application of alginate-based bioinks and coaxial needle system allows for fabrication of 3D hydrogel scaffolds laden with functional islets and vessel-like structures.

INTRODUCTION: Complex pathophysiologies, including skin fibrosis, involve different signalling mechanisms, with a multitude of interconnected potential therapeutic targets [1]. Therefore, there is a need for the development of multi-compartment delivery vehicles for combinatorial and synergistic therapeutic approaches [2]. In this study it was hypothesized that multi-compartment crosslinked collagen type I systems can deliver multiple bioactive agents in a controlled manner in an in vitro model of skin fibrosis.

METHODS: Multi-compartment collagen-based systems were made by mixing dialyzed type I collagen with 10x PBS, followed by neutralisation and crosslinking with 1 and 2.0 mM 4 arm-succinimidyl glutarate ester PEG, respectively, and incubated at 37ºC. The release of encapsulated drugs from the hydrogels was studied by fluorimetry and ELISA and the effect of the delivered bioactive agents was assessed through imaging and quantification for fibrotic markers in a macromolecular crowding induced in vitro model.

CONCLUSIONS: In summary, this indicates that this system is suitable for dual delivery of multiple bioactive agents, resulting in a controlled release in vitro and illustrating its potential in therapy.

Figure 1: (left) A pilot study using FITC-dextran proved that the inner compartment was capable of promoting a sustained release over a long period of time (7 days), which was further confirmed with drug release assays using Trichostatin A, fitting the intended therapeutic release profile. Figure 2: (right) The studied in vitro model showed increased collagen I deposition and α-smooth muscle actin expression, mimicking a fibrotic condition, which was reverted with the use of the designed multi-compartment systems, indicating amelioration of fibrosis.

INTRODUCTION: Tendon rupture repair suffers from the fact that very often mechanically inferior scar tissue is formed during the healing process. This may end up in re-rupture, causing pain and high costs because people cannot go back to work for months. Acceleration of the healing process could counteract the formation of scar tissue and strengthen the tendon at earlier time points post-operation.

METHODS: A full transection rabbit Achilles tendon model was used. A bi-layered electrospun DegraPol® polymer tube, with one layer containing PDGF-BB, was implanted around the conventionally sutured tendon. Emulsion electrospun tubes and coaxially electrospun tubes were fabricated and characterized by SEM, FTIR, and DCS. Their in vitro release kinetics of PDGF-BB were assessed and their in vivo performance was compared with respect to biomechanical, histological and immunohistochemical characteristics three weeks post-operation.

RESULTS & DISCUSSION: PDGF-BB was released in a sustained way (Fig. 1) and was bioactive after release in vitro. Significantly higher load until failure values were obtained for tendons treated with the growth factor PDGF-BB, for both, growth factor released from emulsion electrospun as well as from coaxially electrospun polymer tubes, respectively, when compared to tendons treated with the growth factor-free tube. Cellular distribution in PDGF-BB treated tendons was more homogenous compared to PDGF-BB-free samples. Moreover, the sustained release of PDGF-BB to wound site increased the proteoglycan content and decreased the collagen III intensity as assessed by immunohistochemistry, suggesting an advanced stage of tendon healing. The alpha-SMA expression, acting as a marker for fibrosis, was significantly lower in tendons receiving a sustained PDGF-BB delivery compared to samples without this growth factor.

CONCLUSIONS: Collectively, these data clearly illustrate the beneficial effect of a sustained PDGF-BB delivery to the healing Achilles tendon after full transection.

Figure 1: Release kinetics of PDGF-BB in vitro from emulsion electrospun tubes (A) and coaxially electrospun tubes (B).

INTRODUCTION: There is critical unmet need for new vascularized tissues to support or replace injured tissues and organs. Various synthetic and natural materials were already established for use of 2D and 3D in vitro neovascularization assays, however, they still cannot mimic the complex functions of the sum of the extracellular matrix (ECM) in native, intact tissue. Here, we describe an effective method of isolating a human placenta substrate (hpS) that induces the spontaneous formation of an interconnected network of green fluorescence labeled human umbilical vein endothelial cells (gfpHUVEC) in vitro.

METHODS: The substrate was biochemically characterized by using a combination of BCA, DNA and GAG content assays, SDS-PAGE analysis and Western blot, angiogenesis arrays and chromatographic thrombin detection. 2D in vitro cell culture experiments have been performed using HUVEC and NIH3T3 fibroblasts to determine the vasculogenic potential of hpS. Then, 3D in vitro vasculogenesis assays have been performed by seeding gfpHUVEC in a hpS-fibrinogen clot.

RESULTS & DISCUSSION: The total protein content of the substrate was calculated as 1.74±0.26 mg/mL (mean±SD). The DNA remnants were significantly reduced whereas the DNA content was not significantly reduced after extraction when compared to native tissue. On SDS PAGE and angiogenesis array, multiple proteins with angiogenesis-inductive properties were assessed. In 2D in vitro experiments, HUVEC spontaneously differentiate into cell networks when grown on hpS-coated well plates with a significantly higher degree of complexity (number of tubules/junctions; total/mean tube length) when compared to Matrigel™. In 3D in vitro studies using a mix of hpS, fibrinogen, and HUVEC, randomly-oriented 3D cell networks were formed after approximately one week of culture.

CONCLUSIONS: We have established an effective method to isolate multiple proteins with angiogenesis-inductive properties from healthy human placenta tissue (hpS) with various potential applications for TERM. This material could be used as a novel platform for a human-material-based technology, for various 2D and 3D in vitro assays, as a medium supplementation, 3D bio printing, and probably also for clinical applications.

INTRODUCTION: Nanoclays have generated interest in biomaterial design for their ability to enhance the mechanics of biomedical materials such as hydrogels and impart biological function [1]. As well as functioning as physical cross-linkers via interactions with certain polymers, clay interactions with proteins have been applied for sustained localization to promote in vivo tissue regeneration. To date, both clay-biomolecule and polymer-clay nanocomposite strategies have typically sought to harness the negatively charged clay particle surface via exchange or intercalation. As such, biomolecule-clay and polymer-clay interactions are set in competition, potentially limiting the functional enhancements achieved. Here, we apply specific bisphosphonate interactions with clay particle edge sites to develop a class of self-assembling hydrogels and functionalized clay nanoparticles with preserved surface functionality for enhanced BMP mediated bone induction.

METHODS: Physical hydrogels were prepared by interaction of HA derivatized with bisphosphonate (BP) groups and Laponite nanoparticles. Two types of HA-BP derivatives were used in which BP groups were linked either through disulfide bonds (HA-SS-BP) or by thiol-ene addition to HA-SH derivative resulting to multiple BP ligand attachment (HA-BPn) [2]. Gels were formed via mixing with predispersed Laponite nanoparticles (LAP) and tested for mechanical properties via rheology. Release of Cy9 labelled model protein lysozyme was tested in vivo via an in vivo imaging system (iVis) and BMP-2 ectopic bone induction confirmed via micro CT and histology.

RESULTS & DISCUSSION: Laponite bisphosphonate interactions allow physical crosslinking of high water content hyaluronic acid hydrogels. Laponite addition (2% wt. vol.) to a BP functionalized HA yields a stiff gel, while no gel is formed with addition of Laponite to HA alone. Hydrogels incorporating Cy7-lysozyme were implanted into back sub

CONCLUSIONS: Clay-bisphosphonate complexes can generate self-assembling nanocomposite hydrogels that preserve clay surface sites for protein binding.

CRISPR/Cas9 based COL7A1 genomic editing in RDEB via non-viral polymer delivery system

Presenting author: Jonathan O’Keeffe Ahern, jonathan.o-keeffe-ahern@ucdconnect.ie

aCharles Institute of Dermatology, University College Dublin, Dublin 4, Ireland bEpithelial Biomedicine Division, Centro de Investigaciones Energéticas Medioambientales y Tecnológicas, Madrid, Spain

INTRODUCTION: Recessive Dystrophic Epidermolysis Bullosa (RDEB) is a rare skin fragility and blistering disorder characterized by mutations in the COL7A1 gene which encodes Collagen VII, a major component of the anchoring fibrils which act to provide structural integrity to the skin. To date there is no curative treatment, with only palliative measures in existence. Current treatments for RDEB are focussed on ex-vivo usage of CRISPR/Cas9 genomic editing to permanently correct specific mutations in COL7A1. Here we present the establishment of a non-viral polymer-based gene delivery platform for delivering a CRISPR/Cas9 system encompassing a double guide RNA strategy to mediate an exon skipping approach over pathogenic mutations leading to functional recovery of COL7A1[1,2].

METHODS: The HPAE-EB polymer was complexed with CRISPR/Cas9 plasmid encoding a double guide RNA and assessed for biophysical properties (size, surface charge, encapsulation efficiency) which confer advantages to mediate efficient and cytocompatible gene delivery. Optimized polyplex conditions were identified and used to transfect HEK293 and RDEB keratinocytes. Transfection efficiency was assessed by 48 hrs post transfection with GFP and cell viability was measured using AlamarBlue assay. Genomic DNA was harvested 72 hrs post transfection for PCR and Sanger Sequencing confirmation of successful genomic editing.

RESULTS & DISCUSSION: Picogreen encapsulation, Zetasizer and Zetapotential analysis show that the HPAE-EB polymer can bind with the CRISPR/Cas9 plasmid effectively forming small uniform nanoparticles with desired cationic surface charge. RDEB keratinocyte transfections demonstrate the cytocompatible nature of the HPAE-EB and PCR (Fig 2F) displays the desired genomic correction mediating exon 80 skipping over the pathogenic mutation location in COL7A1.

CONCLUSIONS: The data here demonstrates the feasibility of using the HPAE-EB polymer for delivering a CRISPR/Cas9 system to treat mutations in exon 80 for RDEB and highlights the potential for further development towards clinical application.

INTRODUCTION: Titanium is the most widely used material for dental implants due to its good biomechanical properties and osseointegration capacity. However, the integration with soft tissues is crucial to ensure good sealing and avoid bacterial colonisation. The use of protein fragments from the extracellular matrix (ECM) obtained by DNA recombinant techniques can be used to improve cell-material interactions mimicking the natural environment [1]. In this regard, the heparin binding (HBII) fragment from fibronectin (FN) has the capacity to bind several growth factors including TGF-β [2], which is important for fibroblast activation. However, this fragment lacks the capacity to attract cells. The aim of this study was to mutate the DNA sequence of the HBII domain of FN, in order to introduce an RGD motif, thereby functionalizing the Ti surface with this adhesion and cell activation dual activity molecule in order to improve the soft tissue integration.

METHODS: Titanium discs (10 mm diameter) were polished using Al₂O₃ suspension (0.05 µm). Then, surfaces were activated by plasma treatment and silanized using APTES aminosilane. HBII fragment containing the type III12-14 domains of FN was synthesized using DNA recombinant methods. The HBII DNA sequence was mutated using the Quick Change Mutagenesis Kit to generate an RGD sequence in the type III14 domain. Plasma FN and native HBII fragment were used as control. The growth factor binding capacity of functionalized surfaces was evaluated by ELISA. Human foreskin fibroblasts (HFFs) were seeded in serum-free conditions on the different studied samples and cell adhesion (LDH quantification and immunofluorescence staining), proliferation (LDH quantification), activation (α-SMA, qPCR, zymography) and migration were evaluated after 4h and 1, 3 and 7 days.

RESULTS & DISCUSSION: Cells were more spread on RGD-mutated HBII functionalized surfaces compared to native HBII. In addition, fibroblast activation observed by α-SMA staining was improved in RGD-mutated HBII (16.25% of cells) compared to native HBII (8.43%) and full-length FN (2.32%) due to a higher TGF-β binding capacity. Higher secretion of ECM molecules and ECM remodeling enzymes was also observed in RGD-mutated HBII functionalized surfaces, where cells migrated faster compared to native HBII and FN functionalized surfaces.

CONCLUSIONS: Collectively, the results demonstrate the potential of the novel molecule for soft tissue integration of Titanium implants.

Dimensionality dictates substrate mechanics effects on adipogenesis by controlling Yap phosphorylation through cell spreading

Presenting Author: Jorge Oliver-De La Cruz, Oliver.jorge@fnusa.cz

INTRODUCTION: Although mechanoregulated protein YAP is known to be involved in the adipogenic/osteogenic switch of mesenchymal stem cells (MSCs) [1,2], whether the mechanics of the matrix drives MSC commitment towards one given phenotype by regulating its shuttling, phosphorylation and turnover is not fully understood yet.

METHODS: Immortalized adipose tissue-derived mesenchymal stem cells (AD-MSCs) were exploited to produce cell lines expressing the mutant hyperactive form of YAP (YAP-5SA) and/or a reporter construct which results in the production of mCherry protein under the control of YAP-TEAD binding sites. These cells were challenged for adipogenesis in environments with defined mechanical properties through different bioengineering tools, including micropatterned surfaces and fibrin gels with different stiffnesses.

RESULTS & DISCUSSION: Mechanical regulation of MSC adipogenesis requires YAP repression through phosphorylation, regardless of the presence of a permissive biological environment. This mechanically-driven regulation of MSC fate is mediated by a combinatorial effect of F-actin remodeling and the tension produced by Myosin II motor protein on YAP localization. This phenomenon occurs independently of focal adhesion stabilization and TEAD transcriptional activity and is purely mediated by cell spreading downstream of substrate mechanics, as dictated by dimensionality.

CONCLUSIONS: YAP transcriptional activity, as determined by cell ability to spread over or within a permissive environment, regulates MSC differentiation.

INTRODUCTION: A lot of efforts have been directed to the creation of functional tissues and organs in the lab. The lack of tissue regeneration in human beings and the deficiency of allogenic transplants in addition to the increasing of life expectancy make this problem to be considered as one of the most important ones of humanity in the current era. However, the results obtained are still far away from the desired. Many groups are working on improving the resolution of the systems to be able to directly print something with the same structure of a living tissue. We think that this approach is not going to be successful. For the creation of a living tissue it is crucial the bioprinting process but also the maturation of the construct. Replicating the human being adult conditions in vivo in the lab or the stimuli that occur in embryogenesis could improve the results of tissue engineering towards the clinical application of the technology.

METHODS: Here we propose a unique approach to create functional tissues starting from bioprinted constructs (fabricated using bioprinting) and a device that mimic the physiology and apply the right mechanical conditions of the structure to be replaced and through the maturation procedure, applying the right stimuli, creates a functional tissues. The stress distribution generator is based on the principle of Finite Element Method (FEM) in which loads are transferred in 3D using equations to represent the conditions that happens in reality. We think that the best stress distribution is the real one, and other approaches fail as do not mimic the real conditions happening in nature.

RESULTS & DISCUSSION: In the present work we show a method that helps to create functional tissues after bioprinting. For the creation of a living tissue it is crucial the bioprinting process and the ingredients selected to achieve the objective to create a functional specific tissue. But also the maturation procedure applied to the 3D cell laden constructs, that is even more important. If we think about bioprinting as a technology to recreate all the structure in the same form as shown in a living tissue, we are going to fail. We have to think on bioprinting as a way of creating cell laden 3D constructs as a precursor of a functional tissue. The maturation and tissue formation process will be as important or even more than the bioprinting one. Considering the strategies of both blocks in the diagram will be crucial to obtain the desired functional tissue. Here we present the results of the extracellular matrix created by different types of cells and scaffold structures and applying different mechanical stimuli and physiological conditions.

CONCLUSIONS: The stress distribution is crucial as stimuli to create the right tissue. Also, the scaffold architecture as it will affect the stimuli distribution and other important parameters as the biodegradation time. The selection of the right ingredients and the bioprinting procedure is very important in the success of the creation of functional living tissues, as well as the maturation procedure applied to the 3D cell laden constructs is even more important. This approach opens a wide research area for tissue engineers to develop protocols with different stimuli to create functional tissues after bioprinting.
Tunable collagen-PEG microgels synthesized by 3D printing and microfluidics

Presenting Author: Jose Manuel Rey, jose.manuelrey@collagensolutions.com
1Collagen Solutions, PLC., Glasgow, United Kingdom 2Centre for the Cellular Microenvironment (CeMi), University of Glasgow, Glasgow, United Kingdom

INTRODUCTION: During recent years, microgels have emerged as an effective type of drug delivery system (DDS), showing advantages such as tuneable size, increased surface area and injectability1. The current study focuses on the adaptation of two scalable technologies, microfluidics and bioprinting, for the generation of monodisperse type-I collagen microgels crosslinked with PEG-4S, for regenerative therapies in Parkinson’s Disease and bone repair by encapsulation of different growth factors.

METHODS: Type-I collagen (Collagen Solutions, UK) was neutralized and crosslinked with 4S-Star-PEG succinimide glutarate (Jenkem, USA) to form microgels in a PDMS microfluidic device with flow focusing configuration; and in a 3D Discovery® commercial 3D-printer by successive deposition of collagen and crosslinker solution on a hydrophobic Teflon® surface. Microgel size and mechanical properties were tuned varying the inlet channel/syringe diametre, flow speeds/pressure, pH and concentration of collagen and crosslinker. Microgels were characterized with rheological measurements, TNBSA assay and their cytotoxicity with LIVE-DEAD® assay using Neu-7 astrocytes (n=3).

RESULTS & DISCUSSION: Microgels with different size and stiffness were successfully synthetized in a PDMS microfluidic device and by 3D-printing. The microgels are non-cytotoxic to cells and foster cell growth at different crosslinker concentrations. The typical output of each technique is 30 particles/min by 3D printing versus 600 particles/min using microfluidics, though these values can be increased for instance by parallelization.

CONCLUSIONS: We demonstrate that microfluidics and 3D-printing are adequate techniques for automatically generating monodisperse collagen microgels and provide a reliable tool for the posterior encapsulation of nanospheres and cells. The combination of microgels encapsulating nanometer-sized liposomes is expected to provide a controlled and sustained delivery system of different therapeutic factors.

ACKNOWLEDGEMENTS: The authors would like to thank European Union Horizon 2020 Programme (H2020-MSCA-ITN-2015) and Grant Agreement No. 676408 for providing financial support to this project.

Differentiation of patient matched adipose and bone marrow derived mesenchymal stem cells in an injectable hydrogel for intervertebral disc and bone repair

J Snuggs1, A Thorpe1, S Partridge1, C Sammon1, C Le Maitre1
Presenting Author: Snuggs, Joseph, J.Snuggs@shu.ac.uk

1Sheffield Hallam University, Sheffield, UK

INTRODUCTION: We have previously reported the development of an injectable synthetic Laponite® crosslinked pNIPAM-co-DMAc hydrogel that can deliver and induce nucleus pulposus (NP) differentiation or, with the addition of hydroxyapatite nanoparticles (HAPna), osteogenic differentiation of human mesenchymal stem cells (hMSCs) without the need for any additional growth factors in vitro. This synthetic hydrogel addresses several clinical requirements in one biomaterial, it is biocompatible in the liquid state and enables the safe and homogenous encapsulation of cells and HAPna, the fabrication technique does not require additional chemicals to be added for gelation or clean up and the hydrogel undergoes gelation at body temperature and therefore could use patients’ own MSCs for injection directly into the target site to provide a simplified treatment strategy for intervertebral disc (IVD) degeneration or bone repair and augmentation. As there are multiple sources of hMSCs, this study investigated the incorporation of patient matched hMSCs derived from adipose tissue (AD) and bone marrow (BM) to determine their ability to differentiate within both hydrogel systems under different culture conditions.

METHODS: Human FP and BM derived MSCs were isolated from femoral heads of patients undergoing hip replacement surgery for osteoarthritis with informed consent. MSCs were expanded in monolayer before being encapsulated into either NPgel or Bgel (containing 0.5mg/mL HAPna) and cultured for up to 6 weeks in 5% (NPgel) or 21% (Bgel) oxygen concentration. Samples were then fixed and processed before histological staining and immunohistochemistry were utilized to determine extracellular matrix production and phenotypic protein expression.

RESULTS & DISCUSSION: Both AD and BM derived MSCs were able to differentiate into both cell lineages. NPgel culture conditions increased expression of matrix components such as collagen II and aggrecan and NP phenotypic markers FOXF1 and PAX1, whereas when hMSCs from both sources were cultured under Bgel conditions, the expression of collagen I and osteopontin was increased, indicative of osteogenic differentiation.

CONCLUSIONS: In agreement with previous findings our hydrogel system was able to induce NP and osteogenic differentiation of MSCs, dependant on the addition of compounds and culture conditions. Further to this we were able to show that both AD and BM derived MSCs can differentiate into both NP and osteogenic lineages, highlighting the versatility of this hydrogel when specific cells are cultured under precise conditions. Both NPgel and Bgel have the ability to differentiate patient derived MSCs from different sources into both NP and osteogenic lineages, which may give rise to novel treatment strategies for IVD degeneration and bone repair and may also tailor such strategies to patients’ circumstances and needs.

3D printed tissue engineered dermis using adipose tissue derived minimally manipulated autologous extracellular matrix (MA-ECM) for wound healing and skin regeneration
H. Jo¹, J. Jaeyun Kim¹
¹ROKIT HEALTHCARE, Inc, Seoul, Korea

Accidental skin injury requiring immediate or continuous intervention to restore skin and avoid future complications is ever-increasing worldwide¹. In the U.S alone, 486,000 people received medical treatment for minor burns and 70,000 people were hospitalized for severe skin burn requiring acute care in 2015 according to the American Burn Association¹. Another factor affecting engineered skin market growth is increasing number of patients with skin diseases. Each year over 5.4 million cases of non-melanoma skin cancer are reported and over 3.3 million people are surgically treated in the U.S. in 2014². Numerous wound healing aid products in market help healing process but cannot provide fundamental solutions for severe degree wounds. Although there are several tissue engineered xenogeneic acellular dermal matrix or small intestine submucosa matrix product such as Cytal™ (pig urinary bladder) and Oasis® Wound Matrix respectively, average cost for the treatment is over $6,000 and over $11,000 if living cells are incorporated. Furthermore, average 12 weeks of long healing period to reach 50% healing rate demands significant standard care cost at home and hospital. In case of living cell product either cell seeded matrix or cell injection, extra 2 weeks for cell expansion at the beginning of treatment make these products not applicable to severely wound patients such as soldiers at combat fields who need urgent medical intervention. Therefore, the need for an engineered skin equivalent with improved wound healing efficacy still persists. Recently, adipose tissue gains more attention for potential autologous cell and extracellular matrix (ECM) source that can be used as an engineered skin equivalent material. Stromal vascular fraction (SVF) is a multi-cell complex containing ADSCs (adipose-derived stem cells), fibroblasts, endothelial cells, epithelial cells, macrophages. In addition, as a whole ECM, adipose derived ECM, not treated with any chemical process consists of more than 300 proteins and associated cytokines, provides an optimal 3D biomechanical environment and promotes cell-cell and cell-ECM interaction to stimulate ECM production and vascularization for wound healing/skin regeneration. We developed a technology/procedure that easily separates MA-ECM (minimally manipulated autologous extracellular matrix), cluster of SVF and whole ECM, from liposarpirate and turns those into a custom shaped tissue engineered dermis using 3D bio-printer ‘INVIVO’ (ROKIT HEALTHCARE, Inc, Korea) within 0.5hrs after liposuction. INVIVO 3D bio-printing enables cell printing with uniform density, suture free lamination depending on wound dermis depth, and area depending on wound shape. Large animal (pig) in vivo study confirmed that our skin equivalent consists of MA-ECM showed significantly higher healing rate during the first 2 weeks of post treatment period in full skin defect pig model. Furthermore, nevus removal cases showed a visible scar less healing within 2 week of MA-ECM operation. In conclusion, 3D cell-printed autologous MA-ECM tissue engineered dermis significantly reduced wound closure time and scar formation. We expect this technology opens up new opportunities to provide prompt care in a customized but cost effective way.

INTRODUCTION: Musculoskeletal disorders have a global outreach in the ageing population worldwide and many of them require articular cartilage repair [1]. Human bone marrow stromal stems cells (hBMSCs) are a promising cell source but they pose a serious limitation: subpopulation heterogeneity [2]. We hereby present a proof of concept for high-throughput aggregate formation in microdroplets simulating early chondrogenic condensation, envisioning sorting of hBMSC chondroprogenitor subpopulations.

METHODS: qPCR and immunofluorescence were conducted to study in vitro SOX9 expression in hBMSCs for various cell numbers at the gene and protein level, respectively, as an early chondrogenic functional marker. Human articular chondrocytes (HACs) were included as a human positive control. ATDC5 chondroprogenitor cells in chondrogenic differentiation medium were used for on-chip optimisation purposes, together with hBMSCs. Cells were and injected through the inlets of a PDMS chip with continuous gentle stirring. QX200™ generation oil (Bio-Rad) was used for droplet stabilisation. Droplets were imaged onto a haemocytometer after 6, 24, 48 and 72 h to visualise cell aggregation and viability.

RESULTS & DISCUSSION: Immunofluorescence (IF) assays revealed heterogeneous SOX9 downregulation in hBMSCs from day 7 to day 21 for all cell numbers, whereas HACs maintained SOX9 protein expression. No significant changes were detected in SOX9 expression at early time points set on day 1, 3 and 7 following hBMSC aggregation (p < 0.001), as assessed by qPCR and IF on 500 and 5000 small cell aggregates (n = 3). The droplets generated on the microfluidic platform had volumes ranging from 0.5 to 4 nL (COV < 0.5%). Both ATDC5 and HBMSCs formed aggregates 24 h following encapsulation that remained viable over 72 h of incubation, suggesting the stability of the culture system for early SOX9 screening.

CONCLUSIONS: This work illustrates the high-throughput potential of droplet microfluidics to yield stable aggregates. The absence of fluctuations in SOX9 expression up to one week after aggregation and the droplet volumes attainable accentuate the suitability of this approach with a view to harnessing the hBMSC chondroprogenitor stem cell fraction.

INTRODUCTION: Decellularized tissues can be used to fabricate hydrogels for corneal tissue engineering. However, the effect of the decellularization method on the gel characteristics has not previously been investigated. This study aims to examine the impact of 3 different decellularization protocols on the properties of corneal ECM-derived hydrogels.

METHODS: Three decellularization protocols were compared: SDS (S), Triton X-100 (T), and freeze-thawing cycles (F/T), all followed by incubation with DNAse. These were compared to a control group with no treatment (N) and a rat tail collagen type I gel (C). The parameters analyzed were decellularization efficiency, presence of ECM components, gelation kinetics, mechanical properties, ultrastructure and cytocompatibility using human corneal stromal cells.

RESULTS & DISCUSSION: All treatments removed significant amounts of DNA but only S removed sGAG significantly (Fig 1A). Collagen levels remained constant in all treatments. This was visually confirmed by histological staining. SDS-PAGE analysis showed the presence of collagen and other smaller proteins. Western blotting determined the presence of Keratocan, a typical component of the corneal ECM (Fig 1B). Gelation kinetics was determined by turbidimetric analysis. All treatments yielded slower gelling materials than commercially available collagen. F/T produced the fastest gelling material of all treatments, while S was the slowest (Fig 1C). Corneal stromal cells embedded in the hydrogels presented high cell viability as seen by the gel contraction activity, except for the S treatment, which rendered cytotoxic gels, presumably due to inefficient washing (Fig 1D).

CONCLUSIONS: This study highlights the importance of the decellularization method used to make ECM-derived hydrogels. From our results, F/T is the best method as the gelation time is the shortest, DNA removal is acceptable and loss of sGAG is minimal. Further research will focus on the use of these gels for the repair of small wounds on the ocular surface caused by trauma such as splintering.

Figure 1: A) Biochemical analysis of DNA content (top) and sGAG content (bottom); B) Protein composition via SDS-PAGE (top) and Western Blot analysis of keratocan (bottom); C) Gelation kinetics; and D) Contraction assay

INTRODUCTION: Once a medical implant is implanted into the body, the host reactions can delay or even prevent the integration resulting in implant failure. The main reasons for implant failure are excessive inflammation, infection and lack of integration. In tissue engineering, there is a constant need for the development of surface coatings that can be applied on the implants with bioactive properties. Natural materials with their intrinsic properties close to the ECM microenvironment such as gelatin, hyaluronic acid are good candidates to develop biomimetic hydrogel. These hydrogels can be then functionalized with cytokines, growth factors and bioactive nanoparticles to give them improved bioactive properties. In the current study, we demonstrate the immunomodulatory properties of functionalized gelatin hydrogels in vitro and in vivo

METHODS: Gelatin, Gelatin/HA derivatives hydrogels enzymatically crosslinked have been developed to coat implant surfaces by spin-coating or dip-coating. Hydrogels were characterized using confocal microscopy, SEM. Inflammation and angiogenic markers were quantified with ELISA tests and PCR. An in vivo study was also performed on rats to study the effect of gelatin immunomodulatory coating applied at the surface of 3D printed tracheal patches and the inflammation was checked with histology, immunohistochemistry and cytokine readouts.

RESULTS & DISCUSSION: It was shown that Gelatin/HA-tyramine surface coating can act as a reservoir for anti-inflammatory (IL-4) and pro-angiogenic (VEGF) and then release these molecules to modulate the immune response and promote vascularization1. In an in vivo study on 24 rats, gelatin hydrogel loaded with anti-inflammatory cocktails (IL-10, PGE-2) was applied on the surface of tracheal patches. It was shown that this immunomodulatory hydrogel has significant effect on rat survival, upregulation of anti-inflammatory macrophages (M2) and reduction of inflammatory response.

CONCLUSIONS: Collectively, these data illustrate the possibility of conferring a multitude of beneficial biological properties to gelatin hydrogels to use them as an interface to promote implant integration.

INTRODUCTION: To combat the rising costs and timelines of drug development, human engineered tissues can be used as miniature models of their respective organs to prescreen a drug’s safety and efficacy in-vitro, providing human data before the drug is actually at the clinical stages of development. These physiologically relevant organ-on-a-chip platforms require the development of additional methodologies to functionally integrate the tissues, for studies of the human-on-a-chip, in a way that preserves their individual biological fidelity.

MATERIALS AND METHODS: We designed a series of custom bioreactors to first develop and mature each of the five tissues separately, using a single human induced pluripotent stem (iPS) cell line to develop all tissues, enabling patient-specific human-on-a-chip studies for personalized medicine approaches and the development of disease models. Upon tissue maturation, the engineered tissues were combined into an integrated platform that was designed to connect each tissue via culture above a vascularized transwell insert, while maintaining the homeostatic tissue specific niche in the tissue culture compartment above.

RESULTS AND DISCUSSION: We demonstrate the advantages of integrating mature engineered tissues in a way that preserves the homeostasis of each tissue while enabling communication between organ systems. The optimization of iPS differentiation protocols to achieve all cell types needed for engineering all of the included tissues will be detailed, with an emphasis on obtaining increased efficiency and cell numbers. To demonstrate the utility of the human-on-a-chip platform, the multi-tissue systemic response to drugs is shown and compared to the individual tissue specific responses. We further characterize the effects of flow versus static culture within the integrated system, where the inclusion of vascular flow within a specified shear stress range promotes endothelial barrier functionality and maintains the separation of tissue specific media. The vascular transwell inserts were optimized to facilitate endothelial barrier establishment while also enabling the transport of immune cells between compartments.

CONCLUSIONS: The development of methods to functionally integrate mature organ-on-a-chip systems in a way that promotes physiological relevance will enable future studies of the human-on-a-chip. By using a single patient iPS cell line to derive all tissue systems, patient-specific studies can be investigated. These methods can be further utilized as tools to mechanistically understand the variations in population specific responses to drugs and disease.

INTRODUCTION: The foreign body response (FBR) is characterized by the deposition of proteins around the surface of an implanted device followed by neutrophil and macrophage infiltration, formation of foreign body giant cells and subsequent deposition of a thick collagen capsule around the material. Current literature has focused on the later stages of the FBR, specifically macrophage and fibroblast activation and collagen deposition [1]. To understand how materials are detected as foreign, we evaluated the foreign body protein corona to investigate which proteins are adsorbing to a material and inducing the FBR.

RESULTS & DISCUSSION: We detected four classes of proteins on the surface of polyethylene microparticles: complement, acute-phase proteins, clotting factors and apolipoproteins. As we previously described an increase in the FBR to materials in the context of traumatic muscle injury as opposed to a non-traumatic subcutaneous implantation [2], we analyzed the role of the clotting cascade in induction of the FBR. In wild type (WT) mice, after 4 weeks post-implantation, subcutaneous alginate microparticles are encased in a thick collagen matrix with dense cellular infiltrate as detected by hematoxylin and eosin, and picrosirius red staining (Fig. 1). In clotting-deficient mice (F8-/-) there is no development of a strong FBR, with a thin collagen capsule around the implant and minimal cellular infiltration. Compared to F8-/- mice, WT mice recruit 50 times as many cells (5.5 million vs 0.1 million, p < 0.0001). Furthermore, by flow cytometry, we detected a lower fraction of macrophages in F8-/- mice compared to WT mice. These data suggest that the clotting cascade is a major mediator of the foreign body response.

CONCLUSIONS: We propose that upon material implantation, the implant acts as a seed for protein deposition that increases local concentration of clotting factors thereby activating the cascade and resulting in the deposition of a fibrin clot around the material. This then signals to macrophages and fibroblasts to be recruited and deposit a dense collagen capsule around the material. We are currently evaluating the chemotactic agents responsible for inducing recruitment of macrophages by the deposited clot on the material surface.

INTRODUCTION: Increasingly there is a need to test functionality, integrity and sterility of cell-based products during manufacture and of the final product prior to transplantation. Raman trapping microscopy (RTM) is a non-invasive, label-free, highly sensitive analytical method for fast identification and monitoring of single cells in solution, within 2D or 3D-tissue. Here, we present RTM as a novel tool for gentle yet highly precise cell analysis in three independent experiments, providing an overview about the large versatility of this method. First, the influence of culture conditions on bone marrow stem cells was analyzed. Second we investigated the characteristics of primary human tracheo-bronchial epithelial cells (hTEC) used to build an engineered 3D human airway mucosa tissue model. And third we used RTM to monitor condition of blood products.

METHODS: First bone marrow stem cells were grown in different media for several days, fixed in 3% PFA and analyzed using RTM. Second Raman spectra were collected within cytoplasma of human airway adenocarcinoma Calu-3 cells and isolated hTEC cells seeded on cell culture dishes with glass bottom. Third a few microliters of erythrocyte and thrombocyte concentrates, respectively were diluted in PBS buffer and Raman spectra were taken at different time points. In all experiments, Principal Component Analysis (PCA) was used for analysis of spectral data.

RESULTS & DISCUSSION: Using bone marrow stem cells grown in different culture media, RTM was able to detect variances between the differently cultured samples and group them into several subgroups although samples were blinded. Second: Comparing Raman spectra of living hTEC and adenocarcinoma Calu-3 cells relevant differences were identified in distinct wave number ranges. Furthermore, we could show that both erythrocytes and thrombocytes have their own Raman profile. In addition, change of Raman spectra with time was consistent with routine quality control studies of decrease in platelet activation capacity as well as with the correlation in metabolic consumption.

CONCLUSIONS: RTM is a fast and non-invasive method requiring less than 500 cells for analysis. Thus, RTM has the potential to become a standard for quality control of cell products and may lead to essential improvements in the field of transfusion medicine.

INTRODUCTION: Efficient reendothelialization of acellular vascular grafts is crucial for graft patency and function. Therefore, a hydrogel for graft coating was developed to create additional anchoring-points for cells and support cell adhesion and migration in a pulsatile bioreactor system. Human placental tissue has major advantages to be used as tissue source in tissue engineering, due to its origin, distinctive vasculature, protein composition and its wide availability as clinical waste product [1,2]. In this study the vasculature from the placental chorion was used as raw material to create placental extracellular matrix hydrogels (pECM-HG) for vascular graft coating and tissue engineering applications.

MATERIAL AND METHODS: pECM-HG were produced by tissue decellularization followed by an enzymatic digestion using acidic pepsin solution. The pECM-HG were biochemically analyzed for DNA residuals and collagen and proteoglycan content was quantified. Rheological tests with different hydrogel concentrations were performed to examine the polymerization behavior of the material. Scanning electron microscopy (SEM) was used to visualize pECM-HG fibrous structures. Cytotoxicity, cell adherence and migration assays were performed. pECM-HG coated acellular vascular grafts were analyzed in a perfusion bioreactor system with regard to endothelial cell attachment during reseeding.

RESULTS & DISCUSSION: pECM-HG showed low amount of DNA residuals and preservation of cell interacting ECM proteins. Rheological measurements showed the formation of 3D hydrogels, dependent on respective pECM-HG concentration. Cell binding and viability assays revealed significantly enhanced cell adherence when seeded on surfaces coated with pECM-HG (p<0.001) compared to controls. Furthermore, cell attachment was increased on vascular grafts coated with Pecm HG compared to uncoated and even fibronectin coated controls.

CONCLUSIONS: We have developed a hydrogel from human vascular tissue with high cytocompatibility. Improved recellularization efficiency on vascular grafts by pECM-HG surface coating will support future experiments in the field of vascular tissue remodeling and regeneration using a pulsatile flow bioreactor system. In future applications, pECM-HG will be further tested for its potential to be used in 3D cell printing applications and for its regenerative capacities.

INTRODUCTION: Bovine pericardium (BP) is an extensively used biomaterial particularly in the cardiovascular application of bioprosthetic heart valves [1, 2]. However, cytotoxic limitations of the glutaraldehyde treated BP mean no regenerative properties of the tissue in vivo, resulting in a limited lifespan. This study uses a tissue engineering approach to investigate the potential of a decellularized BP (Decell BP) extracellular matrix as a scaffold for the application of a human mesenchymal stem cells (hMSCs) cell sheet [3].

METHODS: Cell sheets of hMSCs formed using a thermoresponsive polymer poly(N-isopropylacrylamide) (PNIPAm) were compared to a cell suspension (1 x 10^15 cells/cm²) seeded onto Decell BP. Characterisation of the ECM structure, attachment and viability of the cell sheet was performed. Histological observations through hematoxylin and eosin (H&E) staining and scanning electron microscopy (SEM) imaging provided qualitative analysis, while the viability and metabolic activity of live/dead and Alamar Blue assays respectively were assessed.

RESULTS & DISCUSSION: Qualitative analysis of H&E staining displayed no gaps between the cell sheet and the decellularized tissue after 7 d. Cytotoxic evaluation of the BP with Live/Dead assay demonstrated strong viability on the Decell BP. There was no significant difference (p<0.05) in the viability of a single cell suspension and cell sheets grown on Decell BP.

CONCLUSIONS: Overall this research displayed Decell BP as a viable scaffold material for the implantation of a cell sheet and demonstrated positive results warranting further research into its application for bioprosthetic heart valves.

INTRODUCTION: Cardiovascular bypass surgery currently applies autologous grafts which brings along certain downsides: Blood vessel harvesting can lead to increased donor site morbidity and the approach might suffer from limited graft availability. Using small-diameter artificial grafts would eliminate these short-term side-effects, however, such substitutes tend to clog more easily in the long term. We argue that this disadvantage can be overcome: Natural tissue regeneration can be promoted by rendering the graft to be biodegradable on a similar time-scale as tissue regeneration takes place. By additionally utilizing a modular material-design principle, we are able to tailor the mechanical and degradation behavior of a graft substitute to specific needs.

METHODS: The polymer-class of thermoplastic polyurethanes (TPUs) was chosen as graft material due to their suitable properties: Linear polymer sections (soft blocks) make the material elastic. These are connected via small, hydrogen-bonding components (chain extenders). The aggregated areas of chain extenders (hard blocks) make the material resilient to mechanical stress. This modular architecture of TPUs enables fine tuning of mechanical and degradation properties through the specific exchange of polymer components. Electrospinning allows for the manufacturing of highly porous grafts, aiding biodegradability. In this process, grafts are fabricated by injecting a polymer solution into a high-voltage electric field and collecting the emerging nano-fibers on a rotating rod.

RESULTS & DISCUSSION: We created a pool of low-toxic, degradable molecular compounds for their application as chain extenders in the polymer. A variety of polymers with altering components and component ratios was synthesized. The materials were fabricated into grafts via electrospinning and tested with respect to their mechanical, degradation, and in vivo and in vitro biocompatibility properties. Obtained results show significant changes in material properties even upon minor component changes. This approach gave new TPU materials with improved mechanical properties, less inflammatory response, and faster degradation speeds. The modular design principle enabled the difficult optimization of the balance between mechanical properties and degradability.

CONCLUSIONS: The new materials derived from the modular design principle give rise to the possibility of customized artificial grafts for bypass surgery.
Evidence of gut-liver crosstalk and gut homeostasis in paracetamol toxicity: An in vitro study using impedance based cellular assay

INTRODUCTION: Drug induced liver injury accounts for approximately one half of all acute liver failure cases, with Paracetamol (APAP) being one of the most reported hepatotoxins [1]. We used an in vitro approach to model APAP transport from gut to liver where metabolic products (NAPQI) can cause hepatocellular damage. Investigating the mechanisms of a gut-liver axis in vitro may contribute to a better understanding of APAP toxicity.

METHODS: The cellular impedance ECIS Z Ω platform was used to study the gut-liver axis and effects of APAP. Caco-2 and HepaRGs were seeded on separate 8W10+E ibidi arrays. The Caco-2 array was collagen coated. Step 1: Previously established concentrations of APAP [2] were applied to confluent Caco-2s (day 10), and impedance monitored for 24 hrs. Step 2: This ‘preconditioned’ culture medium was then transferred to HepaRGs (day 11) for 24 hrs. Step 3: preconditioned culture medium was then transferred from HepaRGs to fresh Caco-2s (day 12) for 24 hrs.

RESULTS & DISCUSSION: Step 1: using an impedance based cellular assay, we show a tightening of barrier function in Caco-2s treated with 20mM APAP. Step 2: only the highest concentration (20mM APAP) shows substantial loss of impedance on hepatocytes. Step 3: we demonstrate that barrier function has become sensitized on Caco-2s with an increase in impedance at 10mM

CONCLUSIONS: This study demonstrates a potential cross-talk between hepatocytes and enterocytes and reveals a homeostatic effect of gut barrier function in presence of APAP. Exposing hepatocytes to toxic levels of APAP taken from Caco-2’s attenuates toxicity at 5 and 10mM concentrations compared to previous study [2] where a dose-dependent loss of tight junctions was observed (5-20mM APAP). Further exposure of preconditioned media on fresh Caco-2s (step 3) shows that tightening of barrier function is now achieved with lower APAP concentration (10mM) to reduce absorption of APAP. It is possible a liver-gut axis regulates APAP absorption through paracrine signals, though more work is needed. This may differ between population phenotypes and potentially be responsible for variability of toxic response in patients with APAP overdose.

INTRODUCTION: Stem cell-based cardiac tissue engineering is a promising strategy to treat cardiac diseases. Yet, the major challenge is to generate mature cardiac tissues. While different external stimulations have been used to induce maturation, here, we report that 3D hydrogels containing conductive polymers or carbon nanotubes intrinsically enhance maturation of human induced pluripotent stem cell (hiPSC)-derived cardiomyocytes without any external stimulation.

METHODS: hiPSCs were differentiated into cardiomyocytes as reported previously [3] and seeded at 3×10⁴ cells/cm² on solubilized pericardial matrix-hydrazide-functionalized multiwall carbon nanotubes (PMCNT-gel) or resuspended at 2.5×10⁷ cells/ml in a collagen-alginate-PEDOT:PSS hydrogel (eCA-gel) and evaluated for two weeks. Beating movies were acquired and analyzed by MUSCLEMOTION plugin for NIH-ImageJ. Tissues were immunostained for sarcomeric α-actinin, cardiac troponin I and connexin 43 as well as DNA (by DAPI).

RESULTS & DISCUSSION: Analysis of beating movies revealed a significant increase in contraction amplitude of hiPSC-derived cardiomyocytes in conductive engineered tissues compared to those without conductive materials. This was accompanied by formation of patches of aligned cells with an improved intercellular coupling evidenced by a significant increase in connexin 43 expression. Importantly, hiPSC-derived cardiomyocytes reached the sarcomeric length of 1.9 µm in eCA-gels (Figure 1) that is close to that of the adult human cardiomyocyte (2.2 µm).

CONCLUSIONS: Collectively, our data show the beneficial outcomes in using conductive materials in order to enhance maturation of engineered cardiac tissues.

Figure 1: hiPSC-derived cardiomyocytes in the engineered cardiac tissues. Cardiac troponin I (violate), sarcomeric α-actinin (green), connexin 43 (red) and DNA (by DAPI blue). Scale bar: 5 µm.

INTRODUCTION: It has been widely postulated that scaffold pore size and crosslinking significantly influence stem cell migration and chondrogenesis. Here we compared 3D ice templated collagen type I scaffolds of different crosslinkings (10%, 30% and 100% carbidimide crosslinking) and pore sizes (80 µm and 170 µm) and established an in vitro and in vivo assay to compare and select biomaterials with migration and chondro-permissive properties.

METHODS: For evaluation of in vitro migration, human bone marrow mesenchymal stem/stromal cells (BM-MSCs) were fluorescently labelled with CFDA-SE and seeded on scaffolds (3mm x 3mm). Then the constructs were cultured in static culture for 10-16 days, followed by fixation in 4% formaldehyde and optically clearing in gradient solution of benzyl alcohol/benzyl benzoate (BABB) and the samples were imaged with a confocal microscope. Chondrogenesis of BM- and synovial MSCs in the scaffolds was analyzed by histology (glycosaminoglycan deposition). Endogenous cell migration and chondrogenesis was assessed in a bovine osteochondral defect model to simulate a joint-like environment and by implanting the biopsy subcutaneously in immunocompromised nude mice for 4 weeks.

RESULTS & DISCUSSION: Collagen scaffolds with 170 µm pore size supported migration of MSCs significantly better than 80 µm pore size scaffolds. Comparing the crosslinking, 10% crosslinked scaffolds supported migration significantly better than 100% crosslinked scaffolds. In the next step, we compared chondrogenesis in 170 µm pore sized scaffolds with 10% and 100% crosslinking. Our results showed that only 10% crosslinked scaffolds were chondro-permissive while 100% crosslinked scaffolds were less suitable for chondrogenesis with both human BM- and synovial MSCs. The potential of these scaffolds to support endogenous stem cell migration and chondrogenesis was investigated by filling the cartilage defect in an osteochondral biopsy with either 10% or 100% crosslinked collagen scaffolds and implanting the biopsy subcutaneously in nude mice. The in vivo results confirmed our in vitro findings and clearly demonstrated that 10% crosslinked 170 µm collagen scaffolds supported migration and chondrogenesis significantly better than 100% crosslinked scaffolds.

CONCLUSIONS: This in vitro 3D system is a promising method for screening of biomaterials to select materials that support migration and chondrogenesis. Using this method, we identified that lower crosslinked, larger pore sized collagen type I scaffolds support migration and chondrogenesis significantly better than smaller pore sized, higher crosslinked scaffolds.

INTRODUCTION: A current issue in vascular graft engineering is the development of a scaffold that is able to substitute the blood vessel and allow its complete regeneration without forming blood clotting. To have functional vessels, a tight lumen has to be formed which facilitates blood flow. In addition, the mechanical properties of the scaffold should match those of the vessel. Techniques such as bioplotting and electrospinning offer a solution in creating improved vascular grafts. However, current bioplotting systems can only create a limited amount of vascular designs due to the need for a supporting structure during the fabrication process. In addition, the filament size in bioplotting might be beneficial for mechanical support, but impairs cell growth to form a lumen. In contrast to bioplotting, electrospinning is able to form scaffolds that support a vascular lumen, but they are difficult to handle and often collapse on their own weight. Here, we developed a 4th axis system which is able to control the diameter of both the supporting and barrier fibers, which can be used for vascular tissue engineering.

METHODS: A 2 mm diameter mandrel was attached to a DC-motor capable of reaching 20.000 rpm. Polycaprolactone (PCL) (Mw 45.000) was molten in a syringe and dispensed on the attached mandrel while the mandrel rotated at 3000 RPM. After the deposition of the thin fibres, the mandrel with fibres was transferred to a custom CNC-machine with a fourth rotary axis, where a script was generated to create the pathway for the supporting fibres. Mechanical assessment such as radial compression, longitudinal tension and three point bending was performed. The supporting fibres were deposited on top of thin fibres and disinfected with 70% ethanol before endothelial cells (HUVEC) were seeded in the lumen of the scaffold.

RESULTS & DISCUSSION: Results showed control over the thin fiber spacing and fiber diameter (15.4 µm ± 0.9 µm). Full control over the deposition of the structural supporting fibers (265 µm ± 19.9 µm) was also achieved. Mechanical testing revealed different mechanical behavior by changing the structural support pattern. Preliminary cell studies showed that seeded HUVECs in the lumen of the scaffold migrated in the course of days towards the outside of the thin fiber membrane.

CONCLUSIONS: The results show a new method to make scaffolds for vascular engineering. The scaffolds show different mechanical behaviors by changing the printing pattern.

Primary human skeletal muscle cells/myoblasts (PHMs) proliferate in vitro and customarily require cell to cell contact for signaling and cell to surface contact for anchoring. Depriving PHMs of these two factors using suspension culture (SuCu) for 48 hours tends to promote reversible cell cycle exit of the PHMs. A different protocol to SuCu used in a recent study from our laboratory has shown that replacing foetal bovine serum (FBS) with Knockout Serum (KOSR, Gibco™) in PHM culture for 10 days without supplementation of any growth factors also tends to drive PHMs into reversible cell cycle exit. The aim here was to compare and then combine these two distinct yet competent in vitro quiescence protocols to form an improved assorted protocol to aid some of the requirements of simulating skeletal muscle regeneration in culture. SuCu with FBS is relatively quick (48 hours) and tends to nudge PHMs into the G0/G1 phase of the cell cycle. However, with SuCu the PHMs while suspended cannot be visualised under a microscope to assess the morphology, unfavorable for interventions and soon after harvesting PHMs lose their quiescent phenotype. In KOSR culture method on the other hand, as PHMs are adhered to the culture flask, morphology can be monitored throughout and is straightforward for interventions. However, this protocol requires 10 days to attain effective quiescence. Since SuCu uses FBS in the preparation of its media, we hypothesised that replacing FBS with KOSR could improve quiescence. We also hypothesised that harvesting PHMs after SuCu and then plating in KOSR media for a brief period could provide stable quiescent PHMs with all the benefits of the KOSR method without requiring 10 days. PHMs were isolated from skeletal muscle biopsies of young and healthy male subjects. Two different suspension culture medias were prepared with either FBS or KOSR. After 48 hours of SuCu, PHMs were harvested using 1x phosphate buffered saline and total RNA was isolated using the phenol-chloroform method. qPCR for Ki67, Myf-5, MyoD and p21 was performed using Sybr Green dye (Applied Biosystems instrument). Gene expression levels in SuCu KOSR were divergent compared to SuCu FBS. Specifically, Ki67, Myf5 and MyoD were significantly down regulated with KOSR, while p21 was upregulated with both protocols. Since Ki67 and Myf5 transcription factors are involved in satellite cell proliferation, the significantly reduced levels indicate the SuCu KOSR protocol is more effective compared to SuCu FBS for inducing in PHMs a state of quiescence. Current experiments are testing the mixed-method protocol of SuCu followed by KOSR culture for a brief period to determine if the timeline can be reduced from 10 days, but still provide stable quiescent PHMs. Achieving effective in vitro quiescence in a relatively brief time frame will enhance the study of skeletal muscle regeneration, including initiation of activation from quiescence and the feedback mechanism utilised to induce a return to quiescence to protect the progenitor cell pool for future episodes of regeneration of the tissue.
Continuous culture of hESCs on thermoresponsive polymer surface

INTRODUCTION: The conventional cell cultivation of human embryonic stem cells (hESCs) is batch-type culture, which is expansive and laborious. Hence, we developed a continuous culture system, which culturing hESCs on thermoresponsive polymer-coated dish surface having low critical solution temperature (LCST) (Fig. 1). hESCs were detached by decreasing the temperature of culture medium, which prevents hESCs suffering from enzymatic digestion.

METHODS: In this study, we designed to proliferate hESCs on thermoresponsive dish surfaces. The thermoresponsive dishes were prepared by coating thermoresponsive polymer, poly(N-isopropylacrylamide-co-butylacrylate) (polyNIPAM-BA). The optimal concentration of polyNIPAM-BA for hESCs detachment by decreasing temperature of the culture medium was investigated. The surface water contact angle measurement and X-ray photoelectron spectroscopy were used to analyze the hydrophilicity and chemical element composition of dishes surface, respectively.

RESULTS & DISCUSSION: hESCs were successfully cultured on the polyNIPAM-BA coated dishes surface, and partially detached from the surface by incubating at low temperature (7-8°C) for 30 minutes. The optimal concentration of polyNIPAM-BA for hESCs detachment by decreasing temperature of the culture medium was 8 mg/ml. Subsequently, hESCs were continuously cultured on the dishes coated with optimal concentration of polyNIPAM-BA for 5-7 cycles. Moreover, hESCs maintained their pluripotency and differentiation ability after 5-10 cycles of continuous cultivation on polyNIPAM-BA coated dishes.

CONCLUSIONS: We successfully cultured hESCs on polyNIPAM-BA coated dishes surface and thermally modulated the cell adhesion and detachment. It would be a great benefit for biomedical engineering after applying the continuous harvest system on 3D culture of hESCs applying thermoresponsive surface.

Figure 1: (left) Concept of continuous stem cell harvest. Figure 2: (right) Immunostaining characterization of hESC (WA09) pluripotency following continuous culture on dishes coated with 8 mg/ml polyNIPAM-BA. The continuous culture protocol consisted of 5 cycles. Expression of pluripotent proteins: Nanog (b), Oct4 (c), SSEA4 (f) and Sox2 (g). Hoechst staining (a and e). Merged images (d from a-c and h from e-g, respectively). The bar represents 100 μm.

INTRODUCTION: Titanium is a common material for the orthopaedic and dental implants. However, an optimal implant should be bioactive towards bone formation and also be bactericidal. Nevertheless, these characteristics are hard to balance without detriment to each other. Thus, here, we employ and antimicrobial high-aspect ratio nanotopography on the Ti scaffolds. Also, we use a simple polymer coating system to help provide osteogenesis on the antimicrobial features. Polyethylacrylate (PEA) can be applied, via plasma polymerization, as a very thin coating, to 2D/3D structures and it causes spontaneous unravelling of fibronectin (FN) upon contact. In the open conformation, FN can be decorated with ultra-low doses of growth factors, such as BMP2. In addition, 3D implant architecture is becoming desirable so that bone modulus can be matched using Ti and cells can be grown inside the scaffold. The selective laser melting technique (SLM) has many advantages to be used to produce scaffolds with different sizes and shapes, with good dimensional accuracy, and good resolution. Here we are focusing on developing antimicrobial/osteogenic 3D surfaces to help with implant lifetime but also to tackle the modulus mismatch between titanium and bone as this leads to implant micromotion and failure.

METHODS: Alkaline hydrothermal treatment was applied to produce an antimicrobial high-aspect ratio nanotopography on the Ti scaffolds. PEA was applied using plasma polymerization at 100 Watts for 90 secs. Scaffolds physical and chemical characteristics were studied using SEM, AFM, WCA, and XPS. MSCs bone mineralisation was examined using Raman spectroscopy, calcein blue, Alizarin red, and Giemsa staining. P. aeruginosa were cultured on the substrates and the number of viable microbial cells was determined by quantitation of the ATP.

RESULTS & DISCUSSION: Ti surfaces with PEA/FN/BMP2 coating showed improved cell growth, adhesion and bone mineralisation compared with uncoated substrates. Moreover, Ti nanowire surfaces showed a decrease of P. aeruginosa adherence based on the ATP reading. The 3D Ti lattices with 900 µm diameter struts and elasticity ~2 GPa had better MSC adhesion and growth as the bone elasticity is around 7-30 GPa, while the 3D/2h TiO₂ showed a potential bactericidal effect on P. aeruginosa.

CONCLUSIONS: We demonstrate the potential to fabricate 3D Ti implants with topographies that reduce microbial viability and polymer coatings that enhance osteogenesis of MSCs in-vitro

INTRODUCTION: SCI is a cureless condition. Combinatory therapies are regarded as a valuable approach to target the acute, post-lesion phase, in view of the complex cascade of pathophysiology events that leads to the final clinical outcome. We designed a treatment solution based on an implantable biomaterial (electrospun PLLA) loaded with ibuprofen and triiodothyronine (T3) to target two main pathogenic events in acute SCI, i.e. inflammation and demyelination.

METHODS: PLLA scaffolds were prepared by electrospinning technology. The drug-loaded PLLA has been characterized in term of drug release over 14 days (HPLC for ibuprofen; UPLC–MS/MS for T3). The anti-inflammatory effects has been tested in vitro by measuring the TNFα and IL-10 synthesis (mRNA expression level by RT-PCR) in the macrophage RAW 264.7 cell line exposed to LPS (ISO10993); the promyelinating properties by measuring the maturation of primary oligodendrocyte precursor cells (OPC). In vivo efficacy has been tested by implanting the drug-loaded-PLLA in the rat model of contusive spinal cord injury (N=15, mild lesion, performed by Impact One impactor at T8). As control, drug-unloaded PLLA was implanted in lesioned rats (N=15). The BBB score for locomotion and gait analysis (performed by the computerized videotracking system CatWalk, Noldus) were used as efficacy primary end-points.

RESULTS & DISCUSSION: We observed the expected time effect (two-ways ANOVA: F (7,216)=12.53, P<0.0001), starting the recovery at day 7. In PLLA-implanted rats, the observed recovery stabilizes from 21PLD, so that non further improvement is observed. On the contrary, in PLLA+Ibu+T3 rats a significant treatment-effect is observed (F (7,216)=7.349, P=0.0073), also according to the analyzed time points (interaction: F (7,216)=2.189, P=0.00363). At the last observational time (49 PLD) only 20% of PLLA-implanted rats reached the BBB score 10, while 60% of PLLA-Ibu-T3 rat reached score 10 and a further 27% reached score 15. This positive effect was also confirmed by the step sequence regulatory index in the gait analysis at post-lesion day 49 (Mann Whitney test, P=0.0097)

CONCLUSIONS: The implant of PLLA electrospun scaffold loaded with ibuprofen and T3 significantly improves the functional locomotion outcome of rat with contusive spinal cord injury.

INTRODUCTION: Although silk fibroin (SF) holds great potential in bone tissue engineering, its capacity to induce osteogenic differentiation is limited; we recently described that the gasotransmitter hydrogen sulfide (H2S) stimulates osteoblast differentiation and bone formation in vivo. In this work silk fibroin scaffolds were functionalized with a common H2S-donor (GYY) and the resulting osteogenic potential was assessed both in 3D cultures with human mesenchymal stromal cells (MSCs) within perfusion bioreactor and in vivo in a murine model of ectopic bone formation.

METHODS: Porous SF scaffolds were produced by solvent casting and particulate leaching method and loaded with GYY at concentrations of 1 and 5% w/v. The newly generated scaffolds (SF-GYY) preserved chemical and physical properties, as assessed by SEM, FT-IR, NMR and different thermal analyses techniques [1]. Moreover, scaffolds dose-dependently released H2S as revealed by amperometri measurements. Human MSCs were seeded into SF scaffold a cultured up to three week in perfusion bioreactor (Cellec Biotech, Basel) and analysed both with historical staining and for osteogenic gene expression by RT-PCR. SF and SF-GYY scaffolds were also implanted subcutaneously in BL6 mice and assessed for osteogenic differentiation of cells.

RESULTS & DISCUSSION: The presence of GYY dose-dependently increased the formation of ALP+, mineralized nodules compared to control SF scaffolds. Moreover, analysis of gene expression for 84 osteogenic genes revealed that, in the presence of GYY, 89% and 68% of genes were upregulated, respectively, at day 7 and day 21 in culture compared to control scaffolds. In particular, our data show that H2S stimulation substantially induced the expression of genes belonging to BMP signaling pathway; Furthermore, SF-GYY showed markedly up-regulated VEGFA expression both at the gene and protein level. Noteworthy, the expression of BGLAP, considered as a prototypical late marker of osteoblast differentiation and bone formation, was also markedly increased in SF-GYY and peaked at D21 reaching a significant 6-fold increase compared to D0 and over 2-fold increase compared to control SF at D21.

CONCLUSIONS: This study demonstrates that loading SF scaffold with H2S donor is a suitable strategy to promote osteoblast differentiation at sites of bone regeneration. We conclude that H2S can significantly improve the efficacy of existing approaches of bone tissue engineering based of SF biomaterials.

INTRODUCTION: Human pluripotent stem cell- derived limbal epithelial stem cells (hPSC-LESCs) are an exhaustless source of cells for regenerative therapy of the corneal epithelium [1], while human adipose stem cells (hASCs) display considerable potential to regenerate the corneal stroma [2]. However, limited strategies exist for the delivery of these therapeutic stem cells with tissue-like cellular organization to the anterior cornea. With the added risks related to suturing of corneal implants, there is a pressing need to develop new tissue adhesive biomaterials for corneal regeneration.

METHODS: Hyaluronic acid (HA) was modified with aldehyde and carbodihiydradize groups to create hydrazone-crosslinking hydrogels, as previously described [3], with further modification of the carbodihiydradize-component by grafting tissue adhesive dopamine (DOPA) moieties. Tissue-like cellular compartmentalization in the implants was established by encapsulating hASCs inside the hydrogels, with subsequent conjugation of thiolated collagen IV or laminin peptides and hPSC-LESC seeding on the hydrogel surface. We performed rheological characterization, measured swelling and transparency of the HA-DOPA gels, and evaluated their in vitro performance with both cell types. The functionality of the organized cell-laden hydrogel implant was studied in an ex vivo porcine cornea organ culture model.

RESULTS & DISCUSSION: The HA-DOPA gels showed remarkable swelling stability and suitable transparency for corneal applications. The encapsulated hASCs in HA-DOPA gels exhibited good proliferation and cell elongation, while the hPSC-LESCs expressed typical limbal epithelial progenitor markers. Importantly, the compartmentalized HA-DOPA implants displayed excellent tissue adhesion when implanted into the porcine corneal organ culture model.

CONCLUSIONS: We have developed a tissue adhesive dopamine-hyaluronic acid hydrogel and shown its proof-of-concept to deliver human stem cells for regeneration of both the corneal epithelium and the underlying stroma. Collectively, these results encourage sutureless implantation of functional stem cells as the next generation of corneal regeneration.

INTRODUCTION: We are developing tissue engineered cartilage grafts to treat articular cartilage defects using autologous nasal chondrocytes¹ in an ongoing phase II clinical trial. Current methods to assess the quality of engineered tissues are destructive, eliminating the possibility of monitoring grafts continuously and only allows for the assessment of a small part of the graft, which may not be representative of the overall quality. Raman spectroscopy, a method that measures the chemical composition of materials, has the potential to comprehensively and nondestructively characterize engineered cartilage.

METHODS: Native nasal cartilage biopsies were measured with Raman spectroscopy. Nasal chondrocytes were isolated from the biopsies, expanded, seeded onto 3D collagen scaffolds, cultured for up to two weeks in chondrogenic conditions, and measured with a Raman spectrometer. Histological safranin O staining and biochemical quantification of proteoglycans, an important component of cartilage, were performed on the samples and the results correlated with the Raman spectra using statistical learning methods.

RESULTS & DISCUSSION: The high and low quality native biopsies could be distinguished with a sensitivity of 82% and specificity of 87%. During the two-week process of engineering cartilage, the Raman spectra of the grafts became more similar to the native cartilage spectra. Semi-quantitative histological scores based on the staining intensity and cell morphology of the engineered cartilages (the highest quality corresponds to a maximum score of six) could be predicted from the Raman spectra with a model using LASSO variable selection and multiple linear regression.

CONCLUSIONS: We show that Raman spectroscopy could be used for nondestructive quality controls to assess the starting materials and final graft quality of tissue engineered cartilage – ensuring product quality and facilitating regulatory compliance.

Shear stress effect on cardiac pathological models
L. Turco¹, N. Karedla², E. Bodenschatz³, M. Tarantola¹

INTRODUCTION: Engineered constructs combined with microtechnologies can be used as reliable in vitro models to study the development of cardiac diseases and the effect of drugs on cellular functions. During left ventricular remodeling (LVR) after cardiac infarction, cells are exposed to increased mechanical loads, in particular shear stress [1]. Due to the lack of experimental tools to quantify the effect that such a stimulation has on cardiac cells, shear stress is often neglected in in vitro and in silico computational models. Thus we investigated the short- and long-term effect of pathological shear stresses on cellular morphology, contractility, and connectivity.

METHODS: Monocultures of 1-2-day-old neonatal ventricular cardiomyocytes and co-cultures with different percentage of cardiac fibroblasts were seeded in channels equipped with electrode arrays (Ibidi, Martinsried) and allowed to reach confluence for 24h. Subsequently, cells were exposed to a continuous laminar flow with different high shear stresses up to 108h. Meanwhile cell passive biological properties, functional and morphological changes were measured and quantified via non-invasive electric cell-substrate impedance spectroscopy. The effect of shear stress on cell size, shape and actin fibers orientation was determined and confocal images were analyzed with a custom-written program.

RESULTS & DISCUSSION: By combining impedance spectroscopy and optical microscopy we showed that pathological values of shear stress stimulation lead to an immediate decrease of cell-substrate distance at the flow-onset, further cell spreading up to 48h and a gradual reorientation of actin fibers along the direction of the flow. Beating frequency and cell-cell connectivity of cardiomyocytes increased under shear stress and presented synchronized contraction. Surprisingly, we observe for the first time contractility in in vitro co-cultures with 9:1 ratio of fibroblasts after shear stimulation, whereas the non-sheared co-cultures did not show any activity.

CONCLUSIONS: We could prove that stimulating cardiac cells with high shear stress is a reliable in vitro model to reproduce pathological conditions in vivo. This underlines the importance of taking into account the presence of high shear stress in experimental and modeling studies to understand the pathophysiology during LVR and its influence on mechanoelectrical coupling.

INTRODUCTION: The recent description of progenitor cells in degenerated intervertebral discs raised the possibility of harnessing their regenerative capacity for endogenous repair¹. Here, we developed an intradiscal polysaccharide microbead-based delivery system for the sequential release of chemokines and nucleopulpogenic factors. This delivery system would contribute to 1) the recruitment of resident progenitors (CXCL12 or CCL5), followed by 2) the differentiation of the mobilized progenitors (TGF-β1 and GDF5), and 3) the subsequent regeneration of Nucleus pulposus (NP).

METHODS: Pullulan microbeads (PMBs) (100µm) were prepared by a simultaneous crosslinking protocol coupled to a water-in-oil emulsification process. Freeze-dried PMBs were loaded with biological factors then release assays were performed at 37°C for 21 days. To determine the bioactivity of released chemokines and growth actors on in vitro cell recruitment and synthesis of NP-like extracellular matrix (ECM), respectively, human mesenchymal stem cells (hMSCs) were cultured in Transwells during 14 days and histological analysis was performed on loaded PMBs and hMSCs aggregates.

RESULTS & DISCUSSION: All factors were successfully adsorbed on PMBs and a burst release within the 1st day was observed. At day 14, 17% and 68% of CXCL12 and CCL5 were released, respectively and at day 21, 20% and 100% of TGF-β1 and GDF5 were released, respectively. MSCs exhibited an increased tendency to migrate and synthesize an NP-like ECM when cultured in presence of PMBs loaded with chemokines or growth factors.

CONCLUSIONS: PMBs are suitable micro-carriers for the controlled loading and release of biological factors that could boost intervertebral disc endogenous repair. Ex vivo demonstration in ovine IVD model is ongoing, then in vivo proof of concept will be performed in an ovine model of spontaneous IVD degeneration.

**INTRODUCTION:** The use of gene therapy to induce the chondrogenic differentiation of autologous cells has shown potential as an alternative to current cartilage repair approaches. However, successful differentiation into healthy, stable cartilage has yet to be achieved, in part due to the lack of an efficient and safe gene delivery system, but also due to a lack of suitable genetic targets.\textsuperscript{1} The aim of this project is to develop a non-viral nucleic acid platform system capable of efficiently co-delivering pDNA, to trigger differentiation of human Mesenchymal Stem Cells (hMSCs) towards cartilage, and microRNA (miRNA), to minimize hypertrophy. This co-delivery system will then be incorporated into previously optimized chondrogenic 3D scaffolds.\textsuperscript{2}

**METHODS:** Dual delivery nanoparticles (NPs) were formulated by mixing miRNA and/or pDNA with GET (Glycosaminoglycan Enhanced Transduction) peptide.\textsuperscript{3} Nucleic acid encapsulation and NP size were characterized. NP-mediated miRNA transfection efficiency was evaluated using a miR-mimic designed to target the mRNA of the housekeeping glyceraldehyde phosphate dehydrogenase (GAPDH). GAPDH mRNA expression levels in hMSCs were measured by PCR. Transfection efficiency was compared to Lipofectamine RNAiMAX (gold standard).

**RESULTS & DISCUSSION:** Gel retardation assays confirmed the complexation of miRNA by GET. GET formed homogeneous NPs with miRNA and pDNA/miRNA of 31 and 52 nm diameter respectively. Simultaneous delivery of the two genetic cargoes in hMSCs did not have an effect on cell viability or NP uptake. GAPDH mRNA expression was significantly reduced (0.1 fold change) when hMSCs were transfected with the pDNA-miRNA-GET formulation, comparable to Lipofectamine RNAiMAX (Lipo).

**CONCLUSIONS:** We have successfully developed a NP formulation for the co-delivery of pDNA and miRNA. This represents the first stepping stone in developing an efficient gene therapy that promotes successful, long-term cartilage repair by inducing stable chondrogenesis and inhibiting hypertrophy.

INTRODUCTION: Pancreatic islet transplant therapy is a promising treatment for type 1 diabetes mellitus. The Diabetes Reversing Implants for enhanced Viability and long-term Efficacy (DRIVE) project aims to develop a functionalized biomaterial to encapsulate pancreatic islets with the aim to improve survival and engraftment of the transplanted pancreatic islets. Herein, we discuss the formulation of a hyaluronic acid (HA) based biomaterial functionalized with an oxygen carrier.

METHODS: The oxygen carrier was prepared as an emulsion, characterized by dynamic light scattering, and incorporated into the HA to give oxygen carrier emulgels (β-gel). The β-gel formulations were characterized rheologically and oxygen properties were assessed using an oxygen sensor. INS-1E cells were used to form pseudoislets (PIs) for in vitro testing. The INS-1E cells and PIs were encapsulated in the lead β-gel formulation and transferred to a shell; cells encapsulated in a HA gel in a shell were used as a control. A serial glucose stimulated insulin secretion assay of low-high-low concentration glucose was performed on encapsulated cells at 24h, 72h, and 168h following encapsulation and the results were read using a rat insulin ELISA.

RESULTS & DISCUSSION: The oxygen carrier was successfully prepared as an emulsion and showed stability at 4°C for up to 2 months. The β-gels shear thin substantially with increasing shear stress and show recovery of initial properties following the removal of an applied stress. Preliminary results from encapsulated INS-1E and PIs showed higher concentrations of insulin release in the control HA gel than in the β-gel in normoxia at all time-points.

CONCLUSIONS: A HA based biomaterial was successfully functionalized with an oxygen carrier emulsion. However preliminary in vitro work shows higher insulin release in non-functionalized HA gel than the β-gel in normoxia. Future work will focus on repeating in vitro experiments and testing in hypoxia to better mimic an implant site.

ACKNOWLEDGEMENTS: We would like to thank Professor Maechler from the University of Geneva Medical Center for providing the INS-1E cell line. This project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement number 645991.

INTRODUCTION: Autologous chondrocyte implantation (ACI) therapy has most recently been used to treat articular cartilage defects. A next generation of ACI therapy is now being explored using autologous mesenchymal stem cells (MSCs) derived from the patient’s bone marrow and incorporated into hydrogel biomaterials. We investigated an innovative hydrogel combination of covalently crosslinked PEGylated fibrinogen (PF) [1] and hyaluronic acid (HA) with guest-host (GH) interactions [2].

METHODS: Bone marrow-derived human MSCs (hMSCs) were seeded into different formulations of double-network hydrogel and maintained in 3D culture for 21 days under chondrogenic conditions. Control gels was cultured under regular hMSCs conditions. Each formulation contained 2% GH component in 8 mg/mL PF. To create a variety of viscoelastic hydrogels with different mechanical properties, we added different amounts of polyethylene glycol diacrylate (PEG-DA): 0.2%, 0.5%, 1% and 2%. We examined cell adaptability and viability by performing Live/Dead assay, using calcein/ethidium staining of hMSCs. Moreover, dimethylme-thylene blue (DMMB) assay quantified sulfated-glycosaminoglycan (GAGs) content to evaluate chondrogenic differentiation.

RESULTS & DISCUSSION: Live/dead staining with calcein (green) and ethidium (red) shows that cells were able to create a very well-defined interconnected network, with a relatively high number of viable cells within the hydrogels. Cell differentiation process, partly indicated by GAG production, was normalized by the number of live cells. Two groups, 0.5% and 2% PEG-DA, showed an increase in the mass of GAGs as function of time. Further immunostaining experiments will be performed to verify this relationship.

CONCLUSIONS: The current results illustrate the cell adaptability to this state-of-the-art viscoelastic hydrogel. Along with encouraging viability results, GAG quantification indicates the starting of a successful chondrogenic differentiation pathway.

INTRODUCTION: The development of 3D-printed scaffolds for adipose tissue regeneration has recently gained increasing attention as a result of the exponential growth of lipofilling procedures performed in the clinic[1,2]. However, there remains an urgent medical need to develop materials outperforming the commercially available soft tissue fillers since they lack adipose tissue regeneration potential. In the present work, gelatin has been functionalized with either norbornene or thiol functionalities to enable thiol-ene photoclick chemistry. Subsequently, the hydrogels have been processed via extrusion-based 3D printing thereby resulting in patient-specific scaffolds.

METHODS: Gelatin B was modified with 2.5 equivalents 5-norbornene-2-carboxylic acid or with 5 equivalents N-acetyl-homocysteine thiolactone to obtain GelNB with a degree of substitution (DS) of 53 and GelSH DS72 respectively. Gelatin B modified with methacrylamide functionalities (Gel-MOD DS100) was used as a reference. 3D printing was performed using the Bioplotter pneumatic extrusion printer (Envisiontec, Germany). The 3D-printed scaffolds were physico-chemical characterized in depth. Furthermore, the scaffolds were seeded with adipose tissue-derived stem cells (ASCs) to evaluate the differentiation potential of the ASCs via Bodipy staining.

RESULTS & DISCUSSION Cubical shaped gelatin-based scaffolds were printed. The results of the compression tests showed that the Young’s modulus of the GelNB - GelSH scaffolds was 1 kPa compared to 1.5 kPa for Gel-MOD. These values are in the same range as the young’s modulus of native adipose breast tissue (2 kPa). Furthermore, the mass swelling ratio of the GelNB – GelSH scaffolds was 2 times higher compared to the Gel-MOD constructs (i.e. 52 versus 25). The differentiation potential of both scaffolds was assessed using Bodipy staining. On day 7, small lipid droplets could be seen in the cytoplasmic rim of the Gel-MOD and GelNB – GelSH scaffolds cultured in adipose medium, whereas no differentiation was observed on the scaffolds in the control medium.

CONCLUSIONS: The physico-chemical properties of the scaffolds are comparable with those of native adipose tissue. Furthermore, differentiation into the adipogenic lineage was observed in both Gel-MOD and GelNB – GelSH scaffolds. It can thus be concluded that the developed GelNB – GelSH scaffolds can be a promising candidate for adipose tissue engineering applications.

ACKNOWLEDGEMENTS: Liesbeth Tytgat would like to thank FWO for providing her a PhD fellowship.

INTRODUCTION: Orthodontic tooth movement (OTM) occurs when under the mechanical forces. The premise of this process is alveolar bone remodeling and OPG/RANKL/RANK axis plays an important role [1-3]. The purpose of this study is to investigate whether MicroRNA-21 can affect OPG/RANKL/RANK axis then affect tooth movement in mice.

METHODS: We established the orthodontic tooth movement model in C57BL/6 mice and miRNA21 knockout mice. Micro CT, H&E staining and TRAP staining was taken to investigate how miRNA21 affect the tooth movement. We also tested RANKL level in serum by ELISA. CD4+ T cells were isolated from spleen of the wild type mice then treated the miRNA21 knockout mice.

RESULTS: We found that the speed of orthodontic tooth movement was slowed down in miR-21-/- mice. TRAP staining showed that osteoclasts number was decreased, RANKL in serum was also much at a lower level in miR-21-/- mice. Further more, we found CD4+ T cells could partially rescue the OTM in miR-21-/- mice. Further studies showed TNF-α/RANKL pathway involved in miR-21-/- reduced OTM. It suggested that miR-21 promote RANKL secretion by active T cells then influent the maturity of osteoclasts and orthodontic tooth movement.

CONCLUSIONS: microRNA 21 promotes orthodontic tooth movement via TNF-α/ RANKL pathway in T cells. These findings provided an important evidence to understand the systemic factors in orthodontic tooth movement.

INTRODUCTION: Osteoarthritis has become one of the most popular degenerative disease in the world. Based on the efficiency of magnesium ions (Mg²⁺) on the treatment of osteoarthritis, we developed a new drug delivery system which can be easily injected into articular cavity to sustainably release magnesium ions for treatment of OA.

METHODS: PLGA was used to encapsule magnesium oxide (MgO) nanoparticles which were hydrophobically modified and homo-dispersed by stearic acid. The most biocompatible ranges of Mg ions concentration were achieved in PLGA-SA-MgO complex leaching solution in vitro. The fluidic complex was injected into rats’ knee joint cavity with osteoarthritis established by meniscus excision. Two and four weeks after surgery, rats knee joint were harvested and histologic sections were then staining by Safranin O/Fast Green and scored by OARSI standard. In vitro, we used IL-1β-incubated SW1353 cells (chondrosarcoma cells) to simulate the osteoarthritis environment. CCK8, Cell flow cytometry, Western Blot and q-PCR were performed for the exploration of possible mechanism.

RESULTS & DISCUSSION: The most biocompatible Mg²⁺ concentrations range from 2mM to 10mM. MgO nanoparticles was modified by stearic acid and then encapsuled in PLGA microspheres. 4 weeks after injecting the complex into rats’ knee joint cavity, the tissue attrition of joint cartilage was significantly relieved. In vitro experiments, Mg²⁺ increased the expression of SOX9 and then activate phosphorylation of Akt through synthesis of p110α(one subunit of PI3K) in SW1353 cells. By activating the PI3K-Akt signal pathway, the apoptosis-specific protein Caspases was inhibited and the chondrocyte was protected from apoptosis.

CONCLUSIONS: In conclusion, 10mM Mg²⁺ are benefit to the treatment of osteoarthritis by anti-apoptosis of chondrocytes. Our preparation of a novel injectable and degradable PLGA-SA-MgO complex with Mg ions sustained releasing can be applied in clinical application for OA treatment.

INTRODUCTION: Mesenchymal stem cell (MSC) therapy offers great hope to articular cartilage repair. Due to the low number of MSCs in adult tissues, further culture expansion is necessary prior to their clinical use. However, the ex vivo expansion process often leads to reduced stem cell potency and poor therapeutic outcome. In this study, we developed a novel strategy to enhance the stem cell potency through extracellular heparan sulfate (HS) glycosaminoglycans, a co-receptor for key growth factors for maintaining MSC stemness (e.g. fibroblast growth factor 2).

METHODS: Bone marrow-derived MSCs were isolated from the iliac crest of 11 young male donors. The stemness of MSCs were assessed by assays for growth capacity, telomere length, colony-forming efficiency, MSC surface antigen expression and tri-lineage potential. The therapeutic potency of MSCs were tested in a critical-sized osteochondral defect created in the femoral trochlear groove of thirty-six NIH nude rats and forty-five immune-compromised micropigs (n=6). Fibrin gel was used to deliver the cells. Masson trichrome and toluidine blue staining as well as immunohistochemical staining for collagen type I and II were performed on the tissue sections, and assessed with ICRS II and O’Driscoll scores. Magnetic Resonance Imaging (MRI) and biomechanical test were further conducted in the pig models.

RESULTS & DISCUSSION: An HS variant (termed HS8) with high affinity to fibroblast growth factor 2 significantly increased the number of population doublings of human MSCs without a reduction in their telomere length, colony-forming efficiency, MSC marker expression or tri-lineage potential. Therapeutically, HS8-expanded MSCs (MSCHS8) applied to the rat osteochondral defects improved healing compared with the control MSCs. Histology analysis showed more hyaline cartilage was regenerated in MSCHS8 treated defects, and >70% of defects achieved high ICRS II and O’Driscoll scores. In comparison, control MSC treatment had less (~50%) defects and no treatment or fibrin treatment had none (0%) achieving high scores. Similar improvement in osteochondral repair with MSCHS8 was also observed in micropig models. MSCHS8 significantly increased ICRS II and O’Driscoll scores, reduced osteochondral lesions assessed by Magnetic Resonance Imaging (MRI) and enhanced biomechanical properties compared with control treatments.

CONCLUSIONS: This study highlights the important role of heparan sulfate glycosaminoglycan in growth factor-mediated stem cell activity and great potential for stem cell therapy.

ACKNOWLEDGEMENTS: Financial support was received from Singapore Ministry of Health’s National Medical Research Council (NMRC/BnB/0003b/2013) and the Biomedical Research Council of Agency for Science, Technology and Research.
Prolonged intra-articular retention of mesenchymal stem cells by advanced microencapsulation for regenerative joint therapies

INTRODUCTION: Intra-articular injection of mesenchymal stem cells (MSCs) show therapeutic regenerative potential for patients with osteoarthritis (OA) by restoring damaged cartilage, reducing pain, and increasing motion range in clinical studies. However, clinical efficacy is still limited, which is likely caused by the rapid clearance of MSCs from the synovial cavity. We hypothesize that prolonging the intra-articular retention of MSCs increases their therapeutic potential. Therefore, we developed an advanced micro-encapsulation technique, specifically aimed at retaining MSCs in the joint, while supporting their viability and activity. The goal herein is to assess if micro-encapsulation of MSCs prolongs their intra-articular retention and increases their therapeutic potential.

METHODS: MSCs were harvested from 12 week old Wistar rats, and labelled with a near infrared (NIR) label. An enzymatically crosslinkable polymer and a microfluidic droplet generator were used to encapsulate MSCs in microgels (eMSCs). Viability and metabolic activity were assessed. Microgels with near-infrared labelled MSCs were intra-artistically injected in healthy 12 week old Wistar rats (n=6). For four months, quantitation of the NIR signal was performed using whole animal NIR-imaging. After 8 and 16 weeks, microgels were retrieved and the presence of NIR signal and viability of the eMSCs was confirmed. Additionally, 12 week old Wistar rats (n=12), were fed a high fat diet and underwent a groove surgery to induce a mild OA phenotype. eMSCs were intra-articularly injected one week after the groove operation. Functional performance of OA rats was investigated using gait analysis. At the end point from both studies, histological analysis was performed to provide greater insight in the process and mechanism of action.

RESULTS & DISCUSSION: Microfluidic encapsulation allowed for the formation of homogenous, monodisperse microgels (diameter 100 μm, cv <5%), which contained ~13 cells/gel. In vitro, the MSCs maintained ~60% of their initial metabolic activity and survived for at least four weeks. In vivo, MSC microencapsulation increased the intra-articular retention from four weeks (signal eMSCs vs naked MSCs: 63% vs 13%) to four months (signal eMSCs vs naked MSCs: 11% vs N.A.). Microgels retrieved from the knee joint contained viable, NIR-positive MSCs, confirming that the NIR signal came from the injected cells. Gait analysis shows an improved function of osteoarthritic rats receiving eMSCs over rats receiving naked MSCs or saline controls. Histological analysis corroborated the data.

CONCLUSIONS: Our study shows that encapsulation of MSCs in microgels increases their intra-articular retention to at least four months, while protecting the MSCs against the harsh environment within the joint. Additionally, eMSCs alleviated osteoarthritic symptoms on a functional level. This approach allows for a single intra-articular injection with a significantly extended retention of therapeutic cells within the intra-articular joint cavity.

INTRODUCTION: Damage to the temporomandibular joint (TMJ) can be a result of osteoarthritis, congenital diseases, trauma, or tumor excision. The surface of the mandibular condyle is composed of a fibrous zone, covering the hypertrophic zone. A multipotent stem cell population that may be used for tissue engineering (TE) purposes of the TMJ, are dental pulp stem cells (DPSCs). They have great proliferative potential as well as cartilage and bone forming capabilities. The aim of this study was to explore the use of DPSCs for engineering the cartilage of the mandibular condyle. This was done by 1) evaluating which isoform of TGF-β induces fibrous cartilage formation, and 2) by engineering layers of cartilage to mimic the native tissue.

METHODS: Human DPSCs were isolated from the third molars of 3 patients, expanded to passage 4 and differentiated for 35 days in pellet cultures in chondrogenic medium containing TGF-β1, 2, or 3. Pellets cultured without TGF-β were used as controls. The fibrous chondrogenic capacity was evaluated by gene expression analysis of collagen type 1 (COL1A1), COL2A1, COL10A1, aggrecan (ACAN), and cartilage oligomeric matrix protein (COMP), and histology. Mimicking the surfacing fibrous layer and hypertrophic zone of the mandibular condyle was done by creating a cell-laden bilayered gelatin methacryloyl (GelMA) hydrogel (ø=5mm). The bottom layer contained bone marrow derived mesenchymal stem cells (BMSCs) and the upper layer contained DPSCs (20*10⁶/mL; h=1 mm/layer). The constructs were chondrogenically differentiated with TGF-β1 for 35 days and evaluated by histological analysis.

RESULTS & DISCUSSION: The differentiation capacity of DPSCs into fibrous tissue was evaluated by comparing the in vitro effects of three TGF-β isoforms. Gene expression levels of COL1A1, COL10A1, ACAN, and COMP were similar between all three isoforms and significantly higher than when the pellets were cultured without TGF-β. COL2A1 was not expressed in any culture condition. Staining with picrosirius red/alcian blue, revealed a collagenous matrix with limited glycosaminoglycan content, in which TGF-β1 showed most favorable regarding matrix deposition and was therefore used in subsequent experiments. By embedding DPSCs and BMSCs in GelMA, we obtained a bilayered cartilage construct. Notably, the deposited fibrous cartilage had similar matrix morphology as that of a native mandibular condyle.

CONCLUSIONS: Based on the expression profiles and morphology of the pellets cultured in various TGF-β isoforms, TGF-β1 appears to be the most favorable growth factor for fibrous chondrogenic differentiation of DPSCs. The generation of a cell-laden bilayered hydrogel construct indicates that DPSCs can be used for TE strategies for mandibular condyle regeneration.

ACKNOWLEDGEMENTS: The authors would like to thank Reilly de Groot for his help with harvesting the dental pulp. This study is financially supported by the AO Foundation (AOCMF-17-17G).
Synergistic enhancement of mesenchymal stem cells differentiation by using a multifunctional peptidic biointerface

INTRODUCTION: Improving the capacity of synthetic biomaterials to induce and guide bone regeneration is a major goal. This may be achieved by combining integrin-binding ligands with growth factors (GFs), such as the osteoinductive bone morphogenetic protein 2 (BMP-2). This approach optimally mimics the healing microenvironment of bone and has been shown to provide synergistic osteogenic effects. Thus, the objective of the present work was to design a novel biomolecular peptidic platform integrating the RGD sequence and a BMP-2 mimetic peptide to synergistically promote the adhesion and osteodifferentiation of MSCs for bone tissue engineering.

METHODS: The multifunctional peptide platform was prepared by solid-phase peptide synthesis and anchored to model glass substrates via chemisorption with catechol groups. Scrambled sequences were used as controls. The surfaces were characterized by means of contact angle, XPS and fluorescence microscopy. The synergistic effect between the two peptides was assessed via cell adhesion, proliferation and differentiation studies with human MSCs.

RESULTS & DISCUSSION: The physicochemical characterization of the biointerfaces demonstrated a successful binding, distribution and stability of the peptidic molecules. The crosstalk between the integrin-binding peptide and the BMP mimetic synergistically enhanced the number of MSCs adhering to the substrates compared to controls. In contrast, cell proliferation was significantly reduced on the biointerfaces, which may be an indication of concomitant differentiation. Indeed, both mineralization (Figure 1) and ALP activity were synergistically increased on RGD/BMP-2 samples in comparison with the presentation of the individual peptide motifs.

CONCLUSIONS: These results demonstrate that simultaneously presenting the RGD sequence and a BMP-2 mimetic peptide, within a molecular-based scaffold, synergistically improves MSC adhesion and differentiation into the osteoblastic lineage, thus opening the way to new biomolecular strategies for engineering bone tissue.

INTRODUCTION: Articular cartilage (AC) is a complex multi-layered structure organized into four zones, namely superficial, middle, deep and calcified layers [1]. Its mechanical properties are varying with depth, and the compression modulus of the superficial and deep zone shows values corresponding to 0.28 ± 0.16 MPa and 0.73 ± 0.26 MPa, respectively [2]. This paper reports preliminary results on mechanically tunable gellan gum/poly (ethylene glycol) di-acrylate hydrogels for mimicking the mechanical properties of such AC zones.

METHODS: Gellan gum (GG, Sigma-Aldrich) was dissolved 1.5 % wt. in deionized water while stirring for 30 min at 80 °C. Then, poly (ethylene glycol) di-acrylate (PEGDA, Mn: 575, Sigma-Aldrich) was added to the GG solution (10 and 15 % wt.), while keeping the temperature at 50 °C. Afterwards, the photoinitiator (Irgacure 2959, 0.5 % wt., Sigma-Aldrich) was added, and the solutions were stirred for 1 h, then degassed. For mechanical testing, each solution was poured in cylindrical wells (diameter: 6 mm, height: 5 mm) and photocrosslinked with UV light (5 and 10 min). Then, samples were immersed in magnesium chloride (MgCl₂·6H₂O, 1 % wt. in deionized water, Sigma-Aldrich) for 10 min and/or culture medium (Dulbecco’s modified eagle medium, DMEM) for 24 h. Each sample underwent compression through an Instron 2444 (load cell: ± 10 N). The Young’s modulus was extracted from the first linear region (up to 10%) of the stress-strain curve. Data were analyzed by means of ANOVA and Tukey’s tests.

RESULTS & DISCUSSION: Compression data revealed values reflecting the ones of the AC superficial zone in case of PEGDA10 (~ 200 kPa), and AC middle zone in case of PEGDA15 (~ 600 kPa), with significant differences between the use of PEGDA10 and PEGDA15 for all formulations (p<0.05). At constant PEGDA concentration, UV exposure time and ionic crosslinking produced a slight change of the modulus.

CONCLUSIONS: The mechanical properties of GG/PEGDA hydrogels can be tuned for matching the stiffness range of the superficial and deep AC zones. These results are promising in view of the fabrication of 3D printed multi-layered structures AC engineering.

ACKNOWLEDGEMENTS: Research supported by the European Commission, through the project ADMAIORA (ADvanced nanocomposite MAterials fOr in situ treatment and ultRAsound-mediated management of osteoarthritis), funded in Horizon 2020 framework. Grant number: 814413.

INTRODUCTION: Volumetric muscle loss (VML) resulting from traumatic incidents drastically decreases muscle regeneration capacity and lacks treatments. Hydrogels are promising therapeutic candidates by providing muscle cells support through tailored mechanical properties and potential injection in the wound for a perfect fill. However, as the regeneration potential requires the implanted hydrogels to be porous to allow cell infiltration, it is crucial to obtain a porosity during or after injection. Recently, we have developed a biocompatible and biodegradable hydrogel composed of poly-lysine dendrimers (DGL) and an elastic derived peptide (EDP), cross-linked by polyethylene glycol (PEG-NHS), which requires a preformed porosity to be colonized by cells and is thus non injectable per se. Therefore, the aims of this study were to investigate the potential of this hydrogel as a candidate for skeletal muscle repair, together with the creation of a spontaneous porosity through a novel effervescent approach, compatible with injection.

METHODS: To determine the most suitable environment for myoblasts, dense hydrogels were prepared by mixing different ratio of DGL and PEG-NHS in PBS with or without EDP, and their mechanical properties measured by DMA. Mouse myoblasts (C2C12) were cultured on the hydrogels in proliferative conditions during 24h. Time-lapsed cell proliferation, spreading and mobility were quantified by image analysis. To obtain a porosity compatible with injection, DGL and PEG-NHS were mixed with a carboxylic acid and a carbonated base at different ratios in the presence of a non-ionic surfactant at various concentrations. Cytotoxity was studied by immersing the porous hydrogels in culture medium for 24h and applying the supernatant onto normal human dermal fibroblasts, followed by a live/dead viability cell assay after 24 and 48 hours.

RESULTS & DISCUSSION: As the hydrogels stiffness could be modulated from 10 to 150kPa, the C2C12 behavior in terms of cell proliferation, spreading and mobility on the support was strongly influenced with highest values observed for 150kPa. Interestingly, the presence of the EDP induced similar behavior but for lower rigidities (70 kPa). These two hydrogels of interest were therefore used to develop an effervescent porous formulation. Herein, a selection of acid/base ratios and specific mixing order to the hydrogel components allowed a strong effervescence, concomitant to the hydrogel cross-linking. As a striking result, an interconnected porosity was created, remnant of the effervescently-generated CO2 bubbles. Interestingly, the molarities of acid and base and the addition of different types of surfactants allow to control the resulting pore size, distribution and interconnectivity throughout the hydrogels. However, cell viability was negatively correlated with increasing concentrations of surfactants and acid/bases couples.

CONCLUSIONS: Through a versatile hydrogel, environments of interest for muscle cells in regard of stiffness and composition were highlighted, while a spontaneous, interconnected and tailorable porosity could be induced through an effervescent approach. Cells viability further comforts their potential for in situ injection. On-going experiments focus on the optimal porosity for muscle cells infiltration along with potential to enhance functional tissue repair.

INTRODUCTION: Limbal stem cell deficiency (LSCD) prevents self-renewing of the corneal epithelium and leads to conjunctivalization and opacification of the corneal surface. Replacement of the epithelium on the eye of a LSCD patient by an in vitro-produced autologous cultured corneal epithelium containing stem cells represents an interesting option to prevent the loss of vision consecutive to LSCD. We tested the hypothesis that limbal stem cells are present in the basal layer of the tissue-engineered epithelium and can recolonize an empty limbus following grafting to a patient with LSCD through the transplantation of autologous cultured corneal epithelial cells.

METHODS: Human corneal epithelial cells (hCECs) were grown as a monolayer in the presence of irradiated fibroblasts of either mouse (i3T3) or human (iHFL) origin and then seeded on tissue-engineered human corneal stromas to allow regeneration of the corneal epithelium. The reconstructed corneas were then exposed to bromodeoxyuridin (BrdU) during 7 days, followed by a chase period of 1, 7 and 21 days. Localization of stem cells was then assessed by indirect immunofluorescence targeting BrdU and keratin 19 (K19). In addition, hCECs were isolated from a limbal biopsy of the contralateral eye of a patient with unilateral LSCD, resulting from a post-shingles neurotrophic keratitis, and cultured in monolayer in the presence of iHFL. The corneal graft was used to treat the affected eye.

RESULTS & DISCUSSION: Twenty-one days after the BrdU pulse, highly positive BrdU cells expressing K19 were observed in the basal epithelial layer of the tissue-engineered epithelium indicating the presence of human corneal epithelial stem cells. The corneal epithelium rebuilt from hCECs grown with iHFL has a more important stem cell population relative to that produced using hCECs co-cultured with i3T3. Moreover, long term restoration of the corneal epithelium was achieved following transplantation of the autologous corneal epithelial graft and relieved the LSCD suggesting that hCECs recolonized the stem cell niche (limbus). A central penetrating keratoplasty was performed in order to replace the damaged stroma. This allowed to recover corneal transparency.

CONCLUSIONS: The tissue-engineered human corneal epithelium possesses a subpopulation of stem cells located in its basal layer that can, once grafted to an eye with LSCD, recolonize the limbus, thus providing permanent restoration of a self-renewing corneal epithelium and reestablishing a clearer vision to the patient.
Segmented microfibers as high-throughput platform to screen 3D cell-materials interactions

INTRODUCTION: We propose a high throughput microfluidic-based platform to screen cell-material interactions in which cells are localized in specific segments along hydrogel microfibers. The segments are representative of a wide range of physiologically relevant 3D tissue engineering microenvironments [1].

METHODS: The segmented microfibers are produced with a flow-focusing chip with three or four inlets by the pulsatile flow of polymeric solutions. The individual segments are made from the solution of the inner channels in which human adipose stem cells are encapsulated. Each cellular segment is then separated by an acellular part. When a microfluidic mixer is used, the composition of the cellular segments can vary along the length of the fiber to create linear gradients of materials and cells. Similarly, without the mixer Janus segments can be formed, with two separated compartments whose size ratio varies along the fiber.

RESULTS & DISCUSSION: The length of the cellular and acellular parts can be independently controlled by changing only the parameters of the process (pressure or flow rate) while the width of the fiber was optimized to ensure optimal nutrient diffusion (300-400 um). The microfiber, from few centimeters to some meters in length, placed on a custom-made transparent spool permits an automated characterization of the cell response and the respective correlation to the original composition of the segment, based on its position along the fiber. Therefore, the identification of the best material/composition for the differentiation of stem cells has been achieved.

CONCLUSIONS: This approach allows the fabrication of multiple separated 3D cell-laden hydrogel-based environments for the screening of cell-materials interactions and selection of the best conditions for the development of improved tissue engineering approaches.

INTRODUCTION: Colorectal cancer (CRC) is the third most common cancer worldwide and liver is the most common site of CRC metastasis. Relevant tissue culture models are needed to study hepatic metastasis derived from CRC as none of the current models mimic the complex metastatic microenvironment [1]. Here we developed a 3D model of CRC-liver metastasis (CRLM) and matched CRC using patient-derived decellularized matrices to study cell-matrix interaction and drug cytotoxicity.

METHODS: Decellularization of patient-derived samples of healthy colon (HC), CRC, healthy liver (HL) and CRLM was performed with a detergent-enzymatic process. Decellularized scaffolds were seeded with CRC cell line HT-29 transfected to express luciferase and use bioluminescence for longitudinal non-disruptive cell tracking.

RESULTS & DISCUSSION: Decellularization preserved tissue-specific biological and ultrastructural properties of CRC and CRLM ECM. Cell proliferation and migration were quantified with bioluminescence for up to 10 days of culture, together with the expression of Ki67, Caspase3 for apoptosis, E-cadherin and Vimentin for epithelial-mesenchymal transition (EMT). The 3D model supported significantly higher cell proliferation and migration in seeded tumour-derived scaffolds compared to matched healthy tissues. Cells cultured in the 3D environment displayed significantly different gene expression profile in respect to 2D cultures. The most represented biological processes in CRLM-seeded scaffolds involved cellular response to stress metabolic processes, to oxygen level and to starvation, demethylation and deacetylation. These data, together with the loss of E-cadherin and increased expression of Vimentin, suggested clear activation of EMT in CRLM seeded scaffolds. Finally, HT-29 cells grown in CRLM scaffolds and exposed to standard 2D IC50 of 5-FU were resistant to the treatment compared to cells cultured in 2D conditions.

CONCLUSIONS: The 3D culture model developed with seeded patient-derived decellularized ECM better recapitulates tissue-specific microenvironmental features compared to 2D culture conditions and represents a relevant model for the study of CRLM.

INTRODUCTION: Current prevailing options for breast volume and nipple areola complex (NAC) reconstruction post-mastectomy are based on different surgical procedures such as autologous skin and adipose tissue flaps, lipofilling or implant based. However, these conventional reconstructive techniques have inconsistent long-term outcomes regarding maintenance of the shape and projection over time and are hindered by multiple post-operative complications, leading to polarizing patient satisfaction rates. To overcome these limitations, our labs developed an innovative approach based on three-dimensional bioprinting approach to accurately deposit cells and biomaterials into precise geometries with the goal of creating anatomically correct biological vascularized adipose tissue and NAC constructs for breast reconstruction.

METHODS: To conduct such research, human fibroblasts, keratinocytes, and adipose derived stem cells combined with human microvascular endothelial cells were mixed in a unique bioink composed of 3 biopolymers and printed with optimal printing conditions and printer functions.

RESULTS & DISCUSSION: Histological characterisation of the 3D bioprinted adipose tissue showed adipocytes cells forming droplets and capillary-like structures homogeneously distributed within the tissue. Nil red staining highlighted the formation of large lipid droplets-containing cells. Immunostaining analysis confirmed the expression of specific mature adipose tissue markers such as FABP4 and perilipin-1 on the surface of lipid droplets. The bioprinted adipose tissue was also able to release adipose tissue-specific adipocytokines and more specifically leptin and adiponectin, demonstrating the functionality of the bioprinted tissue. Additionally, the 3D bioprinted skin was morphologically and biologically representative of the normal human skin. The printed dermis presented a microvascular network expressing CD31 and supported epidermal formation and proliferation to produce a full thickness, well-organized, and terminally differentiated epidermis.

CONCLUSIONS: This work paths the way to the promising development of autologous vascularized adipose tissue and skin for personalized breast volume and NAC reconstruction.

INTRODUCTION: After the introduction of biomaterials into the body, the surface of implants acts as an optimal substrate for bacterial growth, which increases the risk of developing infections. To modulate bacterial-surface interactions and prevent subsequent infections leading to the implant failure, one strategy consists in designing bioactive coatings on the surfaces. Herein, biphosphonated dendrons (BP-D) were deposited covalently on oxide surfaces. The BP-D presented specific -COOH end groups, which enable to easily functionalize the surfaces with antimicrobial biomolecules such as poly(arginine) (PAR) [1, 2]. Hence, promising coatings for antimicrobial applications were designed here.

METHODS: Prior to PAR functionalization, BP-D (1 mg/mL) were coated on the surface of SiO2 sensors and the deposition was analyzed by Quartz Crystal Microbalance (QCM). PAR10 (1 mg/mL) was then grafted through EDC/NHS chemistry. To characterize the grafting on the BP-D coated surfaces, PAR10-FITC was used and the mean intensity of fluorescence was analyzed by fluorescence microscopy (FM), after 24 h incubation in RPMI 1640 medium at 37 °C. Staphylococcus aureus suspension was deposited on the coated surfaces and incubated for 24 h at 37°C. Bacteria adhered to the surfaces were stained using the BacLight RedoxSensor CTC Vitality Kit, fixed with 4 % PFA to be further observed by FM.

RESULTS & DISCUSSION: Through QCM analysis, optimal conditions for BP-D deposition on surfaces were determined (data not shown). The grafting of PAR10-FITC on BP-D was then checked by FM: higher intensity of fluorescence was observed for the peptide covalently grafted than adsorbed. After the incubation of S. aureus on the coated surfaces, results indicated that only PAR10 grafted on BP-D presented a huge decrease of bacterial adhesion.

CONCLUSIONS: Taken together, these results showed the efficacy of PAR10 covalently grafted to BP-D for antimicrobial coating. This constitutes a suitable strategy to functionalize surfaces and contribute to the success of implantable devices.

Growth-arrested adipose-tissue stromal cells and “physiological” hypoxia enhance ex vivo expansion of hematopoietic cells

INTRODUCTION: The efficacy of long-term ex vivo expansion of stem and progenitor cells (HSPCs) is strongly depends on the feeder cell activity to mimic hematopoietic microenvironment [1, 2]. Here we demonstrated, that combination of mitomycin C (mmC)-induced growth arrest and tissue-related O₂ (“physiological” hypoxia) improved stromal capacity of adipose tissue derived stromal cells (ASCs).

METHODS: ASCs were permanently expanded at “physiological” hypoxia (5%) O₂, growth-arrested with mmC and cocultured with cord blood mononuclears as described earlier [3]. Immunophenotyping, multilineage commitment and RT-PCR analysis of mmC-ASCs were performed. Colony forming units (CFUs), cobblestone area forming cell (CAFCs) were used to detect mmC-ASC stromal activity.

RESULTS & DISCUSSION: MmC growth arrest did not affect viability, stromal phenotype and multilineage potential of ASCs permanently expanded at tissue-related O₂. PCR analysis revealed an up-regulation of genes, encoded molecules of cell-cell (ICAM1, HCAM/CD44) and cell-matrix adhesion (ITGs), extracellular matrix production (COLs) and remodeling (MMPs, HAS1) in growth-arrested ASCs at “physiological” hypoxia in comparison with ambient O₂ (20%). The number of ICAM-1 positive ASCs was increased under low O₂ as well. The share of CD34⁺HSPCs, CFU number and CAFC colonies was higher at “physiological” hypoxia (Fig. 1). CAFCs considered as long-term culture-initiating cells (LTC-IC) known to support long-term hematopoiesis restoration in vivo.

CONCLUSIONS: Application of mmC-ASCs and “physiological” hypoxia as a feature of HSPC tissue niche provides pronounced stromal effects with predominance of very primitive HSPCs. That may be on demand to create the effective and controlled methodological approaches that ensure long-term production of a large number of HSPCs for regenerative medicine.

INTRODUCTION: the introduction of 3D printing in tissue engineering has allowed the development of intricated structures with high definition and reproducibility due to a precise control over the deposition of the printed materials. However, printing limitations have not allowed the development of radial porosity and composition gradients to mimic the structure of graded tissues, such as bone. The aim of this work was to develop a printing method based on the integration of additive manufacturing and computer-aided design to prepare porous scaffolds containing distinct compositions and porosities that resemble bone tissue structure.

METHODS: Composite poly(ε-caprolactone) (PCL)-based scaffolds of cylindrical form with radial gradients of hydroxyapatite (HA) (higher in the peripheral) and porosity (higher in the core) were printed using a segmented printing method based on the welding of segments containing discrete compositions and strand widths. Morphological and structural analyses were carried out by microCT and SEM. Mechanical tests were performed using a compressive bench. Scaffold mineralization was evaluated after incubation in simulated body fluid (SBF).

RESULTS & DISCUSSION: Tensile test revealed the integrity of the welded fibers and no fracture observed at 200% strain. Structure analysis showed no differences between the pore and strand size and porosity of each distinct region of the gradient scaffolds compared to homogenous controls. Core (67%) and outer (16%) regions showed porosities similar to human trabecular and cortical bone, respectively. HA distribution was homogeneous within each region and no particle aggregation was observed (Fig. 1). Compressive modulus was in the range of human trabecular bone for all compositions and dependent on pore size and HA content. Mineral deposition was significantly higher in the regions of the scaffolds with higher HA content.

CONCLUSIONS: The developed printing methodology allowed the preparation of discrete regions with composition and structural gradients similar to human bone tissue.

Figure 1: Cross-sectional images generated from microCT reconstructions of multimaterial scaffolds with two (PCL-HA30 and PCL; A) or three (PCL-HA30, PCL-HA15 and PCL; B) distinct regions with specific compositions and pore sizes. Scale bar=500 μm.

¹Department of Chemistry, CICECO – Aveiro Institute of Materials, University of Aveiro, Campus Universitário de Santiago, 3810-193, Aveiro, Portugal

INTRODUCTION: In vitro models capable of closely replicating the matrixial and cellular complexity of the tumor microenvironment (TME) in three-dimensional (3D) platforms are in high demand. In this context, human derived bone-marrow mesenchymal stem cells (hBM-MSCs) have been gathering importance, given their ambiguous influence in tumor progression. Herein, we engineered an hybrid 3D multicellular spheroid (3D-MCTS) based model, combining A549:Fibroblasts:hBM-MSCs with bioinstructive hyaluronan coated microparticles that serve as vehicles for inclusion of tumor-ECM analogous components, and as cell-anchoring hotspots.

METHODS: Distinct ratios of A549, fibroblasts and hBM-MSCs combined with layer-by-layer treated microparticles were seeded in ultra-low adhesion 96-wellplates. Optical microscopy, SEM, histology, viability, necrotic core formation, and CD44 expression analysis were conducted at 7 and 14 days. Optimized conditions were then subject to hBM-MSCs cell-tracking assays and Doxorubicin cytotoxicity screening to access resistance.

RESULTS & DISCUSSION: 3D microspheres provided proper support for cells to self-assemble into compact 3D microtissues and promoted an increase in CD44 expression, as seen in flow-cytometry analysis (p > 0.05). 3D-MCTS size and sphere-like morphology was highly reproducible and tri-culture models presented the characteristic solid tumors necrotic core. hBM-MSCs cells-tracking demonstrated a dynamic behavior dependent on present populations and ratios. Moreover, doxorubicin administration revealed hBM-MSCs positive effect on cytotoxic responses in 3D tri-culture models and in dual cultures of hBM-MSCs:A549 at 10:1 ratio.

CONCLUSIONS: Overall, these findings evidence the relevance of hBM-MSCs and cancer-stromal population inclusion in 3D in vitro tumor models, showcasing the importance of testing different cell-to-cell ratios to mimic tumor heterogeneity. Moreover, triculture 3D-MCTS with Hyaluronan-coated microparticles effectively allowed for the integration of pre-existing TME-ECM similar components

INTRODUCTION: Disruption of the blood spinal cord barrier is fundamental for the poor prognosis following spinal cord injury. Herein, we developed a hydrogel-based approach consisting on the co-culture of adipose-derived stem cells (ASCs) and human umbilical vein endothelial cells (HUVECs) to promote the vascularization of the injury site.

METHODS: Gellan gum modified with GRGDS (GG-GRGDS) was assessed for its angiogenic capacity in comparison to unmodified gellan gum (GG) and collagen (C) using the chick chorioallantoic membrane assay (CAM) for 4 days. Afterwards, we developed a co-culture system using ASCs and HUVECs encapsulated in GG-RGDS to assess its capacity in the neurite outgrowth of DRG explants. Cells were encapsulated in a 1:1 ratio (15000 of each/50 µL of hydrogel) 24 hours before DRG isolation and controls included each cell type cultured alone (using the same densities) and the hydrogel without cells. After DRG seeding, the culture system was maintained during 7 days. Immunocytochemistry allowed to evaluate the growth of neurites and vascular organization of HUVECs.

RESULTS & DISCUSSION: The number of vessels converging towards the hydrogels showed no significant differences between each experimental condition, with GG being followed by C and GG-RGDS. Growth of neurites using GG-RGDS hydrogels demonstrated that neurite occupied area was highest for the co-culture condition, being statistically significant from the condition without cells (p<0.01), similarly to the observed for ASCs. Longest neurite followed the same trend, but without statically significant differences (p<0.05). Interestingly, HUVECs clearly tended to organize into vascular-like structures in the presence of ASCs within the GG-RGDS, demonstrating the beneficial effects of the presence of these mesenchymal stem cells for SCI vascularization.

CONCLUSIONS: Under the experimental conditions reported, GG-RGDS did not promote increased vascularization using the CAM model. Still, GG-RGDS provided a suitable environment for ASCs and HUVECs encapsulation and neurite outgrowth of DRG explants, in which the presence of ASCs appeared to be pivotal for the arrangement of HUVECs in vascular-like structures. This co-culture system using GG-RGDS demonstrated potential to be further evaluated in vivo in SCI animal models for its capacity of supporting neurite outgrowth and vascular organization at the injury site.

INTRODUCTION: Extensive tracheal damage remains an unmet clinical need as implantable treatment options do not adequately restore a fully functional respiratory tract [1]. The major objective of this study was to develop nanofibrous chitosan-coated polycaprolactone (PCL-CS) scaffolds loaded with all-trans retinoic acid (atRA) and to assess their suitability for tracheal tissue engineering including (i) their biocompatibility and (ii) the effect of atRA on the differentiation of respiratory epithelial cells seeded on the scaffolds.

METHODS: 10% PCL and 5% CS were electrospun (Spraybase®) and atRA was incorporated at three different concentrations (10, 1 and 0.1µg/mg of scaffold). Biocompatibility of atRA-loaded PCL-CS scaffolds was assessed using Calu-3 bronchial epithelial cells under air-liquid interface (ALI) for 14 days. Genetic expression of biomarkers for mucus production (MUC5AC) and cilia formation (FOXJ1), immunocytochemistry and transmission electron microscopy (TEM) were all performed to evaluate and determine epithelial differentiation.

RESULTS & DISCUSSION: atRA-loaded PCL-CS fibres were successfully produced by electrospinning with diameters similar to reported native trachea tissue fibres. All atRA concentrations in the scaffolds supported cell growth and demonstrated comparable biocompatibility to drug-free scaffolds. The incorporation of atRA in the PCL-CS fibres enhanced mucin expression over atRA-free scaffolds and ciliation was observed in all the scaffolds groups.

CONCLUSIONS: atRA-loaded PCL-CS fibrous scaffolds were successfully electrospun as a biocompatible material capable of supporting improved airway epithelial cell differentiation and therefore with potential for application in tracheal tissue engineering.

INTRODUCTION: Hyaluronan (HA), a linear polysaccharide ubiquitously present in the human body, is commonly employed in tissue engineering due to good biocompatibility [1]. HA potential to activate immune cells and overall to induce adverse immune response are suggested to be dependent on HA molecular weight (MW). Low MW HA should activate immune cells in contrast to high MW HA. Thus, degradation of high MW HA based hydrogel matrices to low MW HA fragments theoretically could promote inflammatory reactions in the body and have negative impact on regeneration potential of HA based materials. However, some current studies do not support this conception and emphasize the importance of the form of preparation of HA, particularly with respect to its purity and origin.

METHODS: We compared the activation of mouse immune cells by HA samples (100, 500, and 997 kDa) prepared from HA originating from rooster comb, and HA samples (71, 500, and 1000 kDa) prepared from pharmacological grade HA originating from Streptococcus equi.

RESULTS & DISCUSSION: In contrast to established theory, only middle and high MW HA originating from rooster comb induced the production of tumor necrosis factor-α by macrophages and in whole blood. Further, all tested preparations of HA failed to induce the expression of inducible nitric oxide synthase, the production of nitric oxide, or the expression of cyclooxygenase 2 in macrophages and splenocytes [2,3]. Importantly, all HA samples originating from rooster comb were found to be contaminated by endotoxin (up to 1.23 EU/ml).

CONCLUSIONS: Hence, low MW HA did not reveal itself to have significantly higher immunostimulatory activity to mouse immune cells compared to middle and high MW HA [2,3]. Similarly, our other study employing human blood innate immune cells showed only very limited stimulatory potential of low MW HA compared to middle and high MW HA [4]. Thus, this suggest that the theory of significant pro-inflammatory potential of low MW HA should be revised. Overall, low MW HA should not have a significant potential to induce adverse immune inflammatory response.

INTRODUCTION: Iron oxide based magnetic nanoparticles (MNPs) are versatile tools in biology and medicine. MNPs-mediated drug delivery is tested for regenerative medicine (RM) purposes as well as for tumor treatment and diagnostics. Stem cell mediated delivery represents a modality to target remote, metastatic tumors or regenerative sites for controlled drug delivery. The magnetic behavior of MNPs allows their use as contrast agents for MRI. Moreover, remote controlled actuation of MNPs-loaded cells can deliver micro-mechanical stimulation for enhancing adipose derived stem cells differentiation potential.

METHODS: Human adipose derived stem cells (ADSCs) were loaded with proprietary palmitic acid coated magnetite (MNP-PA) ADSCs-MNP-PA complexes were tested for cell viability, proliferative capabilities and magnetic properties. In vitro osteogenic and adipogenic potential of ADSCs-MNP exposed to magnetic field (MF) was tested. ADSCs loaded with MNP-PA and anti-tumor drug mitoxantrone (MIT) were used for in vitro targeting osteosarcoma tissue-like structures.

RESULTS & DISCUSSION: MNP-PA and MNP-MIT were shown to be up-taken by ADSCs. ADSCs-MNP-PA and ADSCs-MNP-PA-MIT complexes retained cell viability and proliferative capabilities compared to non-loaded ADSCs and displayed high magnetization. ADSCs–MNP-PA-MIT were able to target tumor osteosarcoma tissue-like structures in vitro. Distinctly, increased osteogenesis was displayed by ADSC-MNP in MF compared to non-loaded as well as non-MF exposed cells.

CONCLUSIONS: ADSCs loaded with MNP-PA-MIT were able to target tumor osteosarcoma tissue-like structures in vitro. Present results support the design of stem cell mediated delivery of MNP-PA with or without MIT for targeted drug delivery. Also, MF exposure increased osteogenesis in ADSCs-MNPs, fact that needs to be confirmed in vivo.

Figure 1: ADSCs-MNP-PA-MIT complexes target osteosarcoma (OS) three-dimensional structures in vitro. Figure 2 shows an increased osteogenesis in ADSCs-MNPs exposed to remote actuation using MF after 2 days exposure (MF2D) and 7 days exposure (MF7D) compared to non-exposed ADSCs-MNP (MF No).

INTRODUCTION: Material properties are capable of influencing cell behaviour¹. The aim of this study was to examine the influence of tailored microparticle design by varying surface topography on stem cell response, which is critical for their use as cell delivery systems for regenerative medicine applications.

METHODS: Textured PLA microparticles were produced by exploiting phase separation of fusidic acid from PLA during loss of solvent from an oil-in-water emulsion. Fusidic acid then dissolves leaving textured surfaces (Fig 1A). By varying emulsion settings, microparticles of two key morphologies were produced: dimpled ‘golf ball’ and angular morphologies. To investigate the influence of microparticle topography on cell response, a planar presentation of the particles was developed by heat sintering them into discs before cell culture. The influence of topographical features on attachment and proliferation of primary human mesenchymal stem cell (hMSCs) was investigated. Markers of osteogenesis and comparative gene expression analysis were also assessed in the absence of osteo-inductive supplements.

RESULTS & DISCUSSION: Cell morphology was influenced by the different topographies, with cells spreading on smooth surfaces and adopting more rounded morphologies on dimpled microparticles. In the absence of osteo-inductive supplements, cells cultured on microparticles with dimples exhibited notably increased expression of osteocalcin and mineralisation levels relative to smooth microparticles. Differential gene expression was observed for hMSCs on microparticles compared to 2D-cultured controls. A number of genes were also differentially expressed between smooth and dimpled microparticles.

CONCLUSIONS: Topographically-textured microparticles of varying microscale features were used to investigate stem cell adhesion and subsequent differentiation. This study shows the sensitivity of hMSC attachment and differentiation to microparticle surface topography. It highlights the importance of tailoring topographical design of microparticles and offers the opportunity to control stem cell fate by inducing osteogenesis without use of exogenous osteo-inductive factors.

INTRODUCTION: The establishment of a functional musculoskeletal system depends on a well synchronized development of muscle, tendon and cartilage/bone. The transcription factors Scleraxis and Mohawk as well as Tenomodulin (TNMD, Tnmd), a glycoprotein with cleavable C-terminus, have been identified as key players in tenogenesis. The aims of this study were first, to perform a systematic review of publications based on transgenic mouse models to uncover tendon-specific genes, and second, by surgically induced injury of the Achilles tendons of Tnmd knockout (KO) strain to investigate the role of this gene in the tendon repair process.

METHODS: The search for literature was performed via Pubmed using the terms “tendon”, “tendon phenotype”, “mouse knockout” and “transgenic mouse”. For the injury model of Achilles tendon [2], skeletally mature Tnmd wild-type (WT) and Tnmd-KO mice were used and repair outcomes were assessed at day 8, 21 and 100 (n = 8/genotype/time point) by H&E for overall tissue morphology and BrdU staining for cell proliferation. At day 8, tissue sections were stained with perilipin for fat deposition and collagen IV for blood vessels, and with CD68, CD80, CD163 and F4/80 for macrophage detection.

RESULTS & DISCUSSION: Our literature screen revealed 24 tendon-specific genes and in 22 of the respective knockout mouse models, phenotypic changes were detected. Only Scleraxis and TGFbeta-deficient mice presented severe tendon developmental changes, while others, including Tnmd-KO mice, exhibited mild phenotypes [1]. Regarding the Tnmd injury model, histomorphometrical analysis at day 8 revealed inferior scar organization, reduced cell density and large areas filled with fat and blood vessels. Furthermore, Tnmd-KO Achilles tendon scars exhibited an atypical macrophage profile dominated by M1 macrophages. At day 21 and 100, macroscopic observation suggested a persistent delayed repair of the Achilles joint as well as a fattening atrophy of the gastrocnemius muscle. Detailed histomorphometrical analysis of the Achilles tendons at the above time points are currently on the way.

CONCLUSIONS: Our literature search shows that the tendon developmental program is greatly backed up and compensatory effects are common among proteoglycans. Our experimental study demonstrates that the mild phenotype of Tnmd-KO can be greatly challenged by surgical intervention, thus revealing the Tnmd is important for tendon healing as it prevents accumulation of vessels and fat, and regulates the activity of cells during scar formation and remodeling.

INTRODUCTION: Tendon is mainly composed of densely packed collagen type-I fibers and elastic fibers parallelly oriented among them, which contribute for its elastic function, structural integrity and resilience. Tendon tissue engineering strategies have often recreated instructive substrates that mimic the anisotropically aligned nano-to-macro structure of the native tissue. Here, we hypothesize that the incorporation of tropoelastin, the soluble precursor of elastin, as a surface coating of tendon mimetic scaffolds will positively modulate cell performance, influencing stem cell differentiation towards the tenogenic lineage and matrix deposition.

METHODS: Continuous and aligned electrospun nanofiber yarns [1] were functionalized with recombinant mature wild-type human tropoelastin (Weiss Lab, Australia) through polydopamine (PDA) tethering. Uncoated and PDA-coated yarns were used as control groups. The coatings were characterized using different techniques. Cell response was evaluated using human adipose -derived stem cells (hASCs).

RESULTS & DISCUSSION: After 5 days of culture, hASCs were more elongated and spread on tropoelastin-coated samples, in which the cell aspect ratio is significantly superior to the controls (p < 0.001). Immunocytochemistry analysis also suggests that tropoelastin enhances the tenogenic commitment with higher scleraxis expression from day 5 up to day 21, when compared with the other conditions. Additionally, the presence of tropoelastin on the yarns stimulated elastic fiber assembly, with evidence of elastogenesis at day 14 and with visible elastic fibers at day 21, along with collagen type-I deposition. Last, preliminary results suggest that the deposited extracellular matrix presents a higher elastic behavior (p < 0.0001) for the tropoelastin-coated samples, compared with the other samples.

CONCLUSIONS: Overall, data suggests that the presence of tropoelastin enhances tenogenic commitment by hASCs, while induces elastic fiber assembly, relevant for tendons physiology.

INTRODUCTION: Induced pluripotent stem cells (iPSCs) have been considered as a potential alternative source for generating mesenchymal stem cells (MSCs) to meet increasing demands for MSCs in both research and therapeutic applications. Based on the minimal criteria for defining MSCs published by the International Society for Cellular Therapy (ISCT standard) [1], several different protocols have claimed success in the generation of MSCs from iPSCs (iMSCs). However, questions have arisen relating to the phenotypic fidelity of iMSCs because, irrespective of the derivation methods used, the cells generally have less capacity for adipogenic and chondrogenic differentiation compared to primary MSCs. The objective of this study was to understand the cellular mechanism behind these discrepancies.

METHODS: iMSCs were derived using the embryoid body-based outgrowth method. We compared the differentiation ability, immunophenotype and gene expression profiles (GEPs) between multiple iMSC and BM-MSC lines. In addition, the impact of culture expansion on cell state was evaluated.

RESULTS & DISCUSSION: Preliminary characterization confirmed that iMSCs met the ISCT standard. However, in consistent with previous findings, the cells displayed significantly negligible adipogenic and chondrogenic capacity compared to BM-MSCs. GEPs analysis revealed that iMSCs expressed very high levels of vascular progenitor cell (VPC) genes (KDR and MSX2), whereas BM-MSCs had significantly greater levels of PDGFRα, a marker of paraxial mesoderm. These distinct GEPs were maintained during culture expansion, indicating that, unlike BM-MSCs, iMSCs were more closely related to VPCs.

CONCLUSIONS: The current understanding of VPCs provides a rationale to explain why iMSCs could meet the ISCT standard but displayed altered differentiation propensity compared to BM-MSCs. Firstly, VPCs and MSCs have partially overlapping immunophenotype, which makes them indistinguishably when examined by typical MSC markers, including CD73, CD90 and CD105. Secondly, although VPCs can differentiate along the osteogenic, chondrogenic and adipogenic pathways, such lineage commitment may not be accomplished in MSCs preferred differentiation condition, particularly for the latter two.

In summary, our results suggest a lineage misidentification of iMSCs, indicate the inadequacy of using the ISCT standard to distinguish different mesodermal progenitors and emphasize a necessity to validate the iMSCs identity with various lineage markers.

Bioactive mesoporous silica nanoparticles for stem cell differentiation in bone regeneration
M.T. Tavares,1,2 M.B. Oliveira2, V.M. Gaspar2, J.F. Mano,2 J.P. S. Farinha,1 C. Baleizão1
1CQFM, Centro de Química-Física Molecular, IN—Institute of Nanosciences and Nanotechnology, Instituto Superior Técnico, Universidade de Lisboa, Lisboa, Portugal 2Department of Chemistry, CICECO – Aveiro Institute of Materials, University of Aveiro, Campus Universitário de Santiago, 3810-193, Aveiro, Portugal

INTRODUCTION: Stem cells differentiation is usually performed in vitro by exposing stem cells to specific pro-osteogenic pharmaceutics. As an alternative to the inefficient current strategies, one can use carriers containing such factors, which can be internalized by the cells [1]. These factors, once released inside adult stem cells, induce bone cell proliferation and differentiation, and stimulate the expression bone-related proteins [2][3].

METHODS: Bioactive silica mesoporous nanoparticles containing calcium and phosphate ions on their surface and Dexamethasone in their pores (MSN-CaP-Dex) were synthesized by a modified sol-gel method. 100 µg. mL−1 of MSN-CaP-Dex were administered to human bone marrow mesenchymal stem cells (hBMSCs), Nanoparticles uptake, cytotoxicity and osteogenic differentiation potential were evaluated in hBMSCs up to 21 days.

RESULTS & DISCUSSION: The MSN-CaP-Dex NPs were delivered to hBMSCs and successfully internalized after 24 h (Fig.1A). Osteocalcin immunoassays revealed the presence of this early marker (Fig.1B1-3) and mineralization studies evidenced the existence of calcium deposition (Fig.C1-3). Stem cells incubated with MSN-CaP-Dex NPs showed higher levels of alkaline phosphatase at day 7 than the cells with osteogenic medium. All results show a significant difference to basal medium.

CONCLUSIONS: The MSN-CaP-Dex NPs showed the ability to induce osteogenic differentiation to levels similar or even higher than osteogenic supplementation. Therefore, MSN-CaP-Dex bio instructed stem cells towards osteogenic lineage in basal conditions and with a single dose.

Figure 1: A – MSN-CaP-Dex NPs uptake after 24h, (B1-3) osteocalcin immunolabelling after 14 days of culture, (C1-3) Alizarin red mineralization assay after 21 days of culture.

INTRODUCTION: Cardiovascular diseases are the leading cause of death worldwide. The availability of grafts for the treatment of vascular diseases is a real and urgent need. Simulating the three-layered structure of native blood vessel in a biomaterial scaffold is seen as an effective way to mimic the native architecture, the mechanical behavior, and functional features of native arteries. In this study, production and characterization of a novel multi-layered Silk Fibroin Vascular Graft (SF-VG) is reported. In vitro cell interaction studies were performed to investigate the biological response to the device. The results of in vivo preliminary pilot trials on large animals are presented.

METHODS: The SF-VG was manufactured according to a patented technology (WO 2016/067189 A1). Adult Human Coronary Artery Endothelial Cells (HCAECs), Human Aortic Smooth Muscle Cells (HASMCs), and Human Aortic Adventitial Fibroblasts (HAAFs) were used for the in vitro tests. D-Glucose, L-Glutamine, Lactate, the release of type I collagen, and secretion of various cytokines/chemokines were assessed. SF-VGs were implanted along the carotid arteries of female minipigs and sheep and 4 weeks later were explanted and subjected to histopathological analysis.

RESULTS & DISCUSSION: The SF-VG device was manufactured by combining electrospinning and knitting/braiding technologies. Electrospun and textile layers resulted perfectly integrated and did not show slipping or separation when exposed to mechanical stresses. The results of in vitro cell interaction studies demonstrated the biocompatibility of SG-VG. The cumulative curves of consumed glucose and glutamine and released lactate matched the metabolic activities and the expansion of the respective cell populations. HAAF cells significantly curtailed their de novo production of type I Collagen, with a remarkable antifibrogenic upshot, significantly relevant in clinical settings. Interleukin-6 stands out, being the most intensely secreted cytokine. The high basal secretion of Monocyte Chemoattractant Protein-1 and Monocyte Chemoattractant Protein-2 was indicative of a cell proliferation capacity. Interferon gamma-induced protein 10 (known for its antifibrotic and angiostatic properties) and Regulated on Activation, Normal T Cell Expressed and Secreted (known for its ability to regulate leucocyte diapedesis, angiogenesis, and some scarring processes) were expressed at significant levels. Finally, the pilot animal studies showed the feasibility of using SF-VG as vessel grafts in vivo. No lumen stenosis and a persistently good blood flow was observed.

CONCLUSIONS: SF-VG is a small caliber vascular graft entirely made of pure silk fibroin. The fabrication technology allowed manufacturing a multi-layered scaffold characterized by easy handling during surgery and able to avoid the emergence of any biomechanical mismatch at the implantation site. In vitro cell interaction studies showed that the device favor cell adhesion, survival and growth. Long-term in vivo studies to assess the patency and wall restructuration of grafted SF-VGs are already under course in sheep.

ACKNOWLEDGEMENTS: The authors would like to address heartfelt thanks to Dr. Hu Peng (from the First Affiliated Hospital of Zunyi Medical University, China and currently PhD Student in Verona’s Laboratory, Italy) for his skillful handling of human cell lines.
Continuous gradient hydroxyapatite-based 3D additive manufactured scaffolds for bone interface tissue engineering

M. Cámara-Torres¹, R. Sinha¹, A. Sánchez², A. Patelli³, C. Mota¹, L. Moroni¹

INTRODUCTION: Hard-to-soft tissue interfaces, such as bone-to-cartilage, exhibit continuous spatial gradients in extracellular matrix composition, which provide unique structural and mechanical properties in the tissue interface. [1] For instance, the concentration of hydroxyapatite (HA), as one of the main bone components, gradually decreases towards the soft tissue. [2] Here, we aim at creating scaffolds with continuous gradients in HA composition to mimic native hard to soft tissue interfaces. The effect of different HA concentrations on the osteogenic differentiation of human mesenchymal stromal cells (hMSCs) is evaluated.

METHODS: Composites of the copolymer PEOT/PBT with different HA concentrations (45 and 20 wt%) were prepared by solvent blending. Using our newly developed AM technology, continuous gradient scaffolds (pores xy = 500 um, pores z= 250 um) with varied HA concentration from 0 to 45 wt% along the axial direction were fabricated, in which the neat PEOT/PBT (i.e. no HA) and the 45 wt% HA composites were continuously mixed during the printing process. Initially, mono-concentration scaffolds (45, 20 and 0 wt% HA) were seeded with hMSCs and cultured for 35 days in basic (FBS + ASAP) or mineralization media (basic media + bGP + dexamethasone) and evaluated as control scaffolds. DNA content and ALP activity of hMSCs were quantified at different time points. Alizarin red staining (ARS) was assessed at the end of the culture period.

RESULTS & DISCUSSION: DNA quantification demonstrated no significant differences (p<0.05) in cell attachment among scaffolds, in spite of the HA concentration. Importantly, ALP activity measurements (day 14, day 21 and day 35) illustrated a gradual decrease in ALP production over the course of the culture in scaffolds with all HA concentrations, suggesting the bone matrix maturation over time. Moreover, ARS semi-quantification at day 35 showed significant increase in mineralization with increasing HA concentration in scaffolds cultured in both mineralization and basic media. Interestingly, scaffolds with 45% HA cultured in basic media, exhibited as much matrix mineralization as neat PEOT/PBT scaffolds cultured in mineralization media, suggesting the ability of the composite material to promote osteogenesis without the addition of any osteogenic factors.

CONCLUSIONS: These data elucidate the possibility of using continuous HA gradient constructs as novel type of scaffolds for bone tissue interface engineering.

INTRODUCTION: Current therapeutic strategies to manage Tendon/Ligaments injuries are poorly effective. Herein, we focused on novel tissue engineering techniques, including the use of human bone marrow mesenchymal stem cells (hBM-MSCs) and sustained release of growth factors, loaded within a 3D scaffold, as possible methods for tendon repair.

METHODS: The 3D multiphase device, named 3D-HYALOFIB, is formed by a braided hyaluronic elastic band merged with poly-lactic-co-glycolic (PLGA) nanocarriers (200±50 nm) for the controlled release of human Growth Differentiation Factor-5 (hGDF-5) within a fibrin hydrogel seeded with hBM-MSCs. PLGA nanocarriers were fabricated by a proprietary technology and loaded with 130ng/g of hGDF-5. The elastic properties of the braided band (elastic modulus: 6.84±0.02 MPa) allowed cyclic strain delivery to the hBM-MSCs. At different time points, cells tenogenic commitment was evaluated by IHC and qPCR essays.

RESULTS & DISCUSSION: The 3D system was loaded with 100 mg of nanocarriers to deliver 1.5ng/mL/die of hGDF-5 within the 3D structure; a cyclic strain of 10% (4 hours a day) was also applied to transfer a mean load of 9 N with a frequency of 1 Hrz to the tissue-like system along the 11 days of cultivation. The static conditions were also tested. The hBM-MSCs tenogenic commitment was confirmed after 11 days by gene expression of Collagen I (COL1A1: 2.5 fold after 11 days), Scleraxis (SCX-A: 800 fold after 5 days) and Decorin (DCN: 3 fold after 2 days) (Figure 1a) and by immunofluorescence assay with the production of COL1A1 fibers in the extracellular environment (Figure 1b). The dynamic cultivation gave better results and more uniform collagen deposition within the available extracellular volume, nearby the cells. Cytokines gene expression indicated a good cells reaction toward the biomaterials used for 3D-HYALOFIB assembly.

CONCLUSIONS: 3D-HYALOFIB opens concrete perspectives for developing 3D bioengineered models to better understand specific molecular and cellular composition of damaged systems, as well as to develop a functionalized and totally bio-resorbable tendon tissue substitutes.

INTRODUCTION: Osteoarthritis (OA) is a pathological condition that brings to degradation of the articular cartilage. In recent years, human mesenchymal stem cells (hMSCs) are emerging as promising cell therapy candidate for the treatment of this clinical condition. Many studies demonstrate that MSCs attend to tissue repair through secretion of trophic factors.

METHODS: We developed a “donor-to-patient” closed, scalable and automated system for aseptic therapeutic cell manufacturing using a xeno-free (XF) medium. We characterized cells, secretome and extracellular vesicles (EVs) of hMSCs, grown in FBS and in a chemically defined XF medium. We validated also the potential therapeutic benefits of secreted factors, conditioned medium (CM) and EVs isolated from hMSCs cultured in this innovative culture system, for cartilage repair. We treated primary cultures of human Articular Chondrocytes (hACs) with IL-1α to induce an inflammatory process, and with three different concentrations of hMSC-CM for 16 and 48 h. A parallel experiment was performed pre-treating hACs with MSC-EVs for 3h before to induce the inflammation.

RESULTS & DISCUSSION: We demonstrated that our XF system allow to select a highly proliferating-hMSC population with a strong osteogenic potential, both in vitro and in vivo. These cells have a secretion pattern characterized by biological factors involved in homeostasis, wound healing and angiogenesis, beside showing a very strong secretion of EVs. We observed also that under inflammatory condition hACs can internalize and recruit more MSC-derived EVs, especially those derived from cells cultured in our XF system. We investigated the effects of CM and EVs in the activation of different regeneration pathways. We demonstrated that CM derived from MSCs grown in our medium promote a transient inflammation, enhancing levels of IL-6, IL-8, COX-2 and NF-kB, which are then down-regulated, leading to resolution. Our data also showed that our EVs inhibited IL-1α-induced expression of COX-2, indicating their significant anti-inflammatory potential and their protective role in cartilage.

CONCLUSIONS: Our culture system showed to be suitable to isolated hMSCs and cellular product ready-to-use for clinical therapy.

INTRODUCTION: Fibrous structures are widely used in tissue engineering to restore or enhance the normal functions of human tissue. One method used to fabricate micro- and nano-fibers is electrospinning. This technique produces 2D membranes in a simple and rapid way and with several different polymers. Recently, an innovative methodology, thermally induced self-agglomeration (TISA), has emerged to transform electrospun fibers into 3D structures in order to better mimic the natural architecture of the extracellular matrix (ECM) and in turn allow suitable attachment, growth, and proliferation of cells.

METHODS: In this study, nanofibers mats of polycaprolactone (PCL)/chitosan blends using acetic acid/formic acid were fabricated through electrospinning. They were then converted into 3D scaffolds using the methodology TISA, followed by freeze drying (Figure 1).

RESULTS & DISCUSSION: The obtained products were nanofibrous 3D scaffolds with increasing amounts of chitosan (10, 15 and 20%), highly porous (>90%) and with interconnected pores of different sizes. Swelling tests and compression modulus indicated the suitability of the scaffolds for tissue engineering, particularly for cartilage repair. Cell viability studies of the scaffolds was evaluated.

CONCLUSIONS: The similarity of the scaffolds with the ECM in terms of morphology, structure and properties, indicates that the produced architectures are highly promising for their application in musculoskeletal tissue engineering.

INTRODUCTION

Controlled regulation of bone formation and resorption is essential to maintain bone homeostasis. However, these processes are disrupted in several diseases, such as osteoporosis and bone disease associated to multiple myeloma, causing fractures that most often occur in the spine, and lead to pain, long-term disability and death. Current treatments consist predominantly in anti-resorptive drugs that inhibit/prevent bone resorption but are often associated with several side effects. Therefore, the need for new approaches to promote bone homeostasis and regeneration/repair of bone fractures is increasing. Over the past years non-coding RNAs (ncRNAs), including microRNAs (miRNAs) and long ncRNA (lncRNAs), have emerged as important post-transcriptional regulators. In this context, we aim to investigate the impact of miRNAs and lncRNAs in osteogenic differentiation and osteoclastogenesis.

METHODS:

To achieve this goal, ncRNA expression profile was evaluated during osteogenic differentiation in MC3T3 cell line and in primary human Mesenchymal Stem/Stromal Cells (MSC) and during osteoclast differentiation in RAW264.7 cell line and in human monocytes, by RT-qPCR. Next, the biological effect of the most differently expressed ncRNAs was assessed using ncRNA mimics and inhibitors. To evaluate osteoblast-osteoclast crosstalk, osteoblast-derived culture media at day 7 of differentiation was cultured with osteoclasts and it effect was determined. Finally, ncRNA levels were analysed in bone marrow (BM) of a rats surgical induced with a critical size bone defect.

RESULTS & DISCUSSION:

The results showed that miRNAs (miR-195, miR-29a/b/c) are differently expressed during osteogenic differentiation of both MC3T3 cell and human MSC. Also, lncRNA uc.64+, which is an intronic ultraconserved region, is upregulated during osteogenic differentiation in these cell types. Moreover, miR-29 family is altered during osteoclastogenesis of RAW 264.7 and human monocytes isolated from buffy coats. Modulation of miRNA levels, specifically miR-195 inhibition and miR-29, overexpression, in MC3T3 pre-osteoblast cell line lead to an increase of osteogenic differentiation markers and ALP and Alizarin Red O staining (mineralization). Moreover, supernatant from MC3T3-miRNA transfected cells at day 7 of osteogenic differentiation impaired osteoclastogenesis differentiation of RAW 264.7, by altering the number of multinucleated cells and the expression of the osteoclast markers dendritic cell-specific transmembrane protein (DC-STAMP), C-C Motif Chemokine Ligand 2 (CCL2), and Cathepsin K (CTSK). Finally, results show miRNA levels are altered in BM of rats with surgical bone defect.

CONCLUSIONS:

Taken together, our data indicate that ncRNAs have the ability to regulate osteogenic differentiation and osteoclastogenesis and are potential candidates for bone regenerative therapies.

INTRODUCTION: Biodegradable scaffolds are key elements in regenerative medicine. Chitosan (CS) is a natural biocompatible polysaccharide with poor mechanical properties [1]. A way to improve the mechanical properties of CS is by grafting synthetic polymers that exhibit complementary properties along the CS backbone. Polycaprolactone (PCL) is a synthetic biodegradable and biocompatible polyester with good mechanical properties [2]. Herein, we present the synthesis of CS-g-PCL copolymers and the evaluation of their potential for use in bone tissue engineering by examining the osteogenic capability of MC3T3-E1 cells to differentiate to osteoblasts when cultured onto the CS-g-PCL surfaces.

METHODS: CS-g-PCL was synthesized by grafting carboxylic acid end-functionalized PCL chains onto the amine moieties of CS [3]. The chemical structure and the composition of the copolymers were examined by 1HNMR and FT-IR spectroscopies. CS-g-PCL copolymer films were fabricated by spin coating and the biological response of MC3T3-E1 cells on the CS-g-PCL surfaces was examined. The morphology of MC3T3-E1 cells on the material surfaces was examined by scanning electron microscopy, while cell viability on the CS-g-PCL surface was assessed by the PrestoBlue® assay. Finally, the osteogenic potential of MC3T3-E1 cells cultured on the CS-g-PCL surface was evaluated by determining specific early and late markers and comparing them to the TCPS control.

RESULTS & DISCUSSION: CS-g-PCL copolymers were successfully synthesized and their composition was determined by 1HNMR analysis. Cell viability experiments showed that a CS-g-PCL copolymer, of 78 wt% CS content, promotes cell adhesion and proliferation of MC3T3-E1 cells and that the cells retain their characteristic elongated morphology (fig.1a). Furthermore, the study of early markers of osteogenesis demonstrated that the alkaline phosphatase activity levels were significantly higher at both times point compared to TCPS (fig.1b), while collagen secretion was enhanced on day 7. Finally, investigation of the late markers of osteogenesis revealed that calcium biomineralization deposit and osteopontin levels were significantly higher for CS-g-PCL, after 14 days in culture, compared to TCPS [3].

CONCLUSIONS: CS-g-PCL copolymers were successfully synthesized by the ‘grafting to’ technique. Cell culture experiments showed strong cell attachment and proliferation increase of MC3T3-E1 cells on a CS-g-PCL copolymer of 78 wt% CS content compared to control. Moreover, the increased levels of specific osteogenic markers of the pre-osteoblastic cells cultured on the material surface indicate the potential of the CS-g-PCL copolymers for scaffold fabrication in bone tissue engineering.

INTRODUCTION: Biomaterials play a pivotal role in tissue engineering, where cells must migrate to the site of the defect through the matrix scaffolding, then proliferate and facilitate the remodeling. We here aimed to test the influence of different hyaluronan (HA)-based hydrogels on cartilage repair by stimulating joint-resident cells. We first query cell migration in vitro, testing a new Fibrin/HA (FB/HA) formulation and HA/Tyramine hydrogels as material cues in the context of migratory barriers using a 3D spheroids-based assay via provision of platelet-derived growth factor-BB. We then implemented this signal in vivo, using an osteochondral explant as a cartilage defect model system.

METHODS: CFDA-SE-labelled bone marrow hMSCs from 3 donors were seeded to form spheroids of 500 cells, embedded in FB/HA or different HA/Tyr cross-linked density hydrogels (150, 300, 600µM H2O2) and cultured in aMEM, 1%ITS with/without PDGF-BB. Microscopy analysis was employed to measure the migratory area of the cells from the core. In-vitro chondrogenesis in the hydrogel1 was determined by qRT-PCR and histology. Osteochondral defects made in bovine osteochondral biopsies2 were filled with FB/HA and HA/Tyr (150) hydrogels with/without PDGF-BB and subcutaneously implanted in nude mice for 4 weeks.

RESULTS & DISCUSSION: HA hydrogels allowed cell migration from the spheroids in presence of PDGF-BB, inducing progressive increase over three days culture. However, HA/Tyr gels with the lowest crosslinking densities (150µM H2O2) were softer and promoted faster migration than stiffer gels, but FB/HA supported the broadest cells migration area (5-fold increase compared to HA/Tyr hydrogels). Both hydrogels supported in vitro hMSCs chondrogenesis, as shown by collagen II and aggrecan expression. By 4 weeks cells were significantly present in FB/HA gels and reached 85-90% of the scaffold area compared to 30% for HA-Tyr untreated groups (**p<0.01). Consequently, cell mediated matrix remodeling was significantly enhanced in untreated FB/HA gels in comparison to untreated HA-Tyr gels (GAG production, **p<0.01 Fig 2C).

CONCLUSIONS: This study showed a reduction in the size of cartilage lesion and enhanced regeneration of the cartilage using FB/HA hydrogels without exposure of growth factor before implantation. Our system can be employed as advanced platform for pre-clinical screening of biomaterial and for delivering chemoattractants to enhance cartilage repair by endogenous stem cells.

INTRODUCTION: Mesenchymal Stem Cells (MSC) were isolated from adipose tissue of patients with venous leg ulcers for experimental, autologous transplantation. MSC phenotype and their ability to secrete biologically active factors were evaluated.

METHODS: MSC were isolated from a lipoaspirate (n=5) using closed, fully automated CELLUTION 800 system (Cytori Therapeutics, USA). Directly after isolation the phenotype of cells was evaluated by flow cytometry using the FACSCalibur (Becton Dickinson, CA). Secretory profile was evaluated in supernatants with the use of the RayBio Custom C-series human Cytokine Antibody Array.

RESULTS & DISCUSSION: In evaluated samples the percentage of cells expressing the MSC markers CD73+, CD90+ ranged from 65 to 82%. Similarly high percentage of CD34+ cells was found in all samples. About 20% of CD31+ (endothelial) and CD45+ (hematopoietic) cells were observed in samples (Fig.1).

Cells from all patients produced in vitro IL-8, MMP-3, MCP-1, GRO, TGFβ2, TIMP1 and some of them, additionally, Angiopoietin 2 or VEGF (Fig.2).

CONCLUSIONS: The purity of MSC preparations separated by Cellution 800 was above 60%. Unexpectedly, high percentage of cells expressed CD34 antigen. In supernatants from MSC primary cultures several cytokines with angiogenic activity were found.

Figure 1: (left) Phenotype and average percentage of cells separated from patient adipose tissue
Figure 2: (right) Secretion of cytokines by primary cultures of MSC with the use of the RayBio Custom C-series human Cytokine Antibody Array.

Regulation of pericyte function in angiogenesis and tissue regeneration: The role for T-cadherin

INTRODUCTION: Vascularization and formation of stable functional vascular networks within bioengineered tissue grafts are essential requirements for efficient tissue and organ regeneration. Pericytes are mural cells which play a key role in regulation of vessel sprouting, stabilization and maturation during angiogenesis. Cadherins are adhesion molecules controlling morphogenesis and the maintenance of tissue architecture. Until recently, N-cadherin which forms endothelial-pericycle adherens junctions remained the only cadherin described in pericytes. Here we demonstrate the role for another member of the superfamily, atypical GPI-anchored T-cadherin, in regulation of pericycle function.

METHODS: T-cadherin expression in pericytes from heart, brain and adipose tissue was analyzed by immunohistochemistry. Overexpression or silencing of T-cadherin in human cultured pericytes from placental and adipose tissue was achieved using lentiviral vectors. T-cadherin effects on pericytes were analyzed using CyQuant proliferation assay; migration monitored by time-lapse videomicroscopy; invasion in fibrin gel; angiogenesis in Matrigel and in a microfluidic chamber. Pericycle differentiation was studied using flow cytometry analysis of human stromal-vascular fraction (SVF). Gene expression and activity of signaling pathways were measured by qPCR and immunoblotting.

RESULTS & DISCUSSION: T-cadherin is expressed by cultured CD146+/CD34- placental and adipose-tissue pericytes, NG2+ cells from the heart, brain and adipose tissue, and 3G5-antigen+ pericyte-like cells from human aorta. Ectopic T-cadherin expression or silencing in pericytes regulate proliferation, migration, invasion, differentiation and cytoskeleton organization. In cocultures with human endothelial cells from umbilical vein (HUVEC) T-cadherin overexpression promotes and silencing delays pericycle-dependent regulation of endothelial network formation. Changes in T-cadherin expression level modulate expression of pericycle genes relevant for differentiation and angiogenesis, as well as activity of signaling cascades involved in control of pericycle proliferation, migration and phenotype, among them Akt and TGFβ1 pathways. Endogenous T-cadherin expression in pericytes is increased in response to TGFβ1.

CONCLUSIONS: We have identified T-cadherin as a novel regulator of pericycle function. T-cadherin signaling is relevant for control of angiogenesis and vessel maturation and may be a potential target to improve vascularization during tissue engineering and repair.

Dermal equivalents produced with an innovative elasto-mimetic hydrogel
M. Carranca1, J. Sohier1

INTRODUCTION: The dermis is the layer of the skin that provides flexibility and strength to the skin. It is principally composed of fibroblasts, responsible of the production and regulation of the ECM. While collagen is widely used as scaffolds for dermal equivalents, it has weak mechanical properties, batch-to-batch variability and risk of pathogen transfer.[1] This impulse towards the development of new materials for these applications. Interestingly, as well as collagen, the dermal matrix comprises a high amount of elastin, which provide its elasticity.[2] Therefore, we hypothesized that a hydrogel integrating an elastin derived peptide (EDP) with similar physicochemical properties as tropoelastin would be beneficial to recapitulate a dermal equivalent. A hydrogel composed of poly-lysine dendigrafts (DGL) and PEG and encompassing the EDP was therefore developed and evaluated as a support for the formation of an efficient dermal equivalent.

METHODS: Hydrogels were obtained by mixing DGL-G3, PEG-NHS and EDP in PBS and made porous by particulate/leaching technique, using paraffin microspheres as porogens (50-180µm). Dermal equivalents were obtained by seeding human fibroblast for 14, 21 and 42 days in vitamin-c supplemented medium. The quality of the extracellular matrix (ECM) produced through time was evaluated by IHC and zymography. The mechanical properties of the acellular hydrogels were compared with colonized hydrogels through time. To investigate the effect of the EDP, fibroblasts were seeded on 2D hydrogels and observed over 16hrs with time-lapse and IHC.

RESULTS & DISCUSSION: Hydrogel’s mechanical properties can be modified by changing the ratio of DGL/PEG components. Hydrogels with ratio 2/19 present a complex modulus of 14kPa, close to those reported in the literature for skin [3]. Human fibroblasts can homogeneously colonize the hydrogels after 21 days and synthetize their own ECM. Interestingly, unlike collagen gels, no contraction was observed. Cell density in the hydrogels was increased when the EDP was incorporated, and cells were able to infiltrate deeper and produce a greater quantity of collagen. Zymography showed the presence of pro-MMP, but no activation after 8 and 21days.

CONCLUSIONS: A hydrogel containing an EDP allows to efficiently produce a dermis equivalent without retraction. The presence of EDP in the hydrogels improved cellular colonization and proliferation, resulting in a higher synthesis of ECM. Ongoing experiments are characterizing further the ECM quality and eventually produce a full skin equivalent.

INTRODUCTION: Cancer cells from various sources have been reported to express high levels of the 67 kDa laminin receptor, which is responsible for the interactions between cells and laminin of the extracellular matrix [1]. Specifically, the penta-peptide TyrIle-Gly -Ser-Arg (YIGSR), derived from laminin b1 chain, has been identified as the binding site to its cell surface receptor. We have hypothesized that the attachment of YIGSR on the surface of CarboxymethilChitosan (Polyamidoamine) CMCh/PAMAM dendrimer nanoparticles (NPs) would lead to their preferential uptake by metastatic cancer cells over other cells types.

METHODS: CMCh/PAMAM dendrimer NPs were modified using simple EDC chemistry (Fig.1a). After synthesis, NPs were characterized using TEM. NPs size and surface changes were measured using zeta potential (Zeta Sizer) and DLS technologies. The specific internalization of peptide-linked dendrimer NPs by colorectal cancer cells was assessed in standard culture flasks in a co-culture of live stained HCT-116 colorectal cancer cells and L929 fibroblasts.

RESULTS & DISCUSSION: We describe a simple method to covalently link the YIGSR peptide to our dendrimer NPs. DLS results show that the diameter of the modified NPs is increased from 54 nm to 130 nm when compared to the non-modified ones. Similarly, the surface charge is less negative compared to the unmodified NPs. This indicates a reduction in the number of carboxylic acid groups on NP surfaces following the peptide binding. The results indicate a targeted internalization of NPs by the HCT-116 cancer cells after 24h of culture, which may probably be due to the overexpression of laminin receptor. Ongoing experiments aim to quantify the internalization efficiency and specificity after seeding the cancer cells both on 2D and 3D environments.

CONCLUSIONS: Our preliminary results confirm the successful modification of CMCh/PAMAM dendrimer NPs with the peptide using simple EDC chemistry. Next, a preferential internalization of the peptide-modified NPs in HCT-116 cancer cells is observed, in contrast to L929 fibroblasts. We intend to improve the specificity and efficiency of drug-targeted therapies on disseminated metastatic cancers, which are the major drawback in current therapeutic approaches.

INTRODUCTION: The transplantation of insulin-producing cells is a promising therapeutic approach to treat diabetic patients, with potential to restore their quality of life and reduce costs associated with the disease. Transplanted cells targeting the treatment of diabetes are most often obtained from allogeneic sources, which poses the need for lifelong immunosuppressants intake for patients. Immunosuppressing therapies are associated with several pernicious effects. Encapsulation of functional insulin-producing glucose-responsive cells in biomaterials is a plausible technology to circumvent immunosuppression. Those systems provide transplanted cells with a stealth barrier for the immune system. Despite the short-term success of biomaterial-based encapsulating strategies, transplanted cells (namely, pancreatic islets) have shown a decay of function in time periods of one to five years. Current challenges reported for transplantation strategies targeted at the treatment of diabetes may be circumvented through the development of coatings with high biocompatibility, adequate perm-selectivity to warrant immunogenic protection, and capability to promote angiogenesis to enable host-capsule integration.

METHODS: A method based on the deposition of elastin-inspired biomaterials was developed to coat insulin-producing human cells that were obtained by directed in vitro differentiation of human induced pluripotent stem cells. The cutoff of the coatings was extrapolated from diffusion tests using coated alginate beads to withstand the developed coatings. The assembly of the biomaterials used in the build-up of the coatings was assessed using a quartz crystal microbalance with dissipation mode (QCM-D), and the morphology of model films was assessed by microscopy and atomic force microscopy. The deposition of the coatings on cells was confirmed by confocal microscopy. Cell viability and insulin release were assessed after the coating procedure.

RESULTS & DISCUSSION: The biomaterials used for cell coating were detected on cells’ surface by confocal microscopy. For specific cell types an apparently continuous coatings could be detected around the cellular structures. The coating did not impair cellular viability up to 12 days of cell culture. Moreover, insulin passage upon glucose stimulation was also not impaired. Coatings incorporating pro-angiogenic motifs were also successfully developed.

CONCLUSIONS: A method to coat insulin-producing cells was developed without hampering cells’ viability or insulin secretion-associated functionality. The immunoprotective effect of the coating as well as its vascularization-inducing property is expected to be proven in vivo using immunocompetent animal models.

ACKNOWLEDGEMENTS: This project has received funding form the European Union’s Horizon 2020 research and innovation program under grant agreement No 646075.
Engineered human chondrocyte shape correlates with nanoscale cytoskeletal stiffness

**INTRODUCTION:** High throughput image processing and computational analysis are increasingly being used to efficiently quantify cell shape via mathematical shape descriptors for statistically correlating biological form with biological function. Moreover, the standardized engineering of cell shape through micro-patterned adhesion sites, biomaterial stiffness, and biomechanical forces is helpful for better understanding the association of micro-environmental stimuli with cell morphology and associated function. In terms of mechano-transduction, such external stimuli can initiate changes in cytoskeletal properties, which in turn modify focal adhesions and cytoskeletal organization and activate integrin-mediated signal pathways. In this context, we asked how cell shape engineered through micro-contact printed geometrically defined adhesion sites affects the single cell cytoskeletal Young’s Modulus, and which aspect of shape measured by mathematical shape descriptors correlates best with cytoskeletal Young’s Modulus. Such information would be helpful for controlling cell nano-mechanical properties via engineered cell shape.

**METHODS:** H-shaped vs. circular fibronectin micro-printed adhesion site geometries (micro-patterns (MPs)) with comparable areas as well as non-patterned control surfaces were used. Chondrocytes (CHs) isolated from human articular cartilage were cultured on the MPs at a density of 3000 cells/cm\(^2\) overnight. In a combination of life cell imaging and nano-indentation, CHs were indented on top of their nucleus, using the Chiaro Nanoindenter from OPTICS11 coupled to an AxioObserver Z1 (Zeiss) with temperature and atmospheric control. The nano-indentation characteristics included a displacement of 10.000 nm, the tip radius was 3 µm and the tip stiffness was 0.055 N/m.

**RESULTS & DISCUSSION:** The Young’s Modulus of H-shaped CHs was 809±139 Pa, of circular CHs was 1179±207 Pa, and of control CHs was 1471±268 Pa. There was a statistically significant correlation between numerically coded CHs shapes (controls coded as 1, h-shape coded as 2, o-shape coded as 3) with the Young’s Modulus (correlation coefficient: -0.340, p=0.004, n=72 cells; Fig. 1). The difference in the Young’s Modulus between control CHs vs. H-shaped CHs and of control CHs vs. O-shaped CHs was significant (p<0.05). Comparable significant correlations were found between numerically coded CHs shapes vs cell area and also cell length but not cell width, roundness, aspect ratio, circularity, or solidity.

![Figure 1](image.png)

**Figure 1:** Young’s Modulus of shape-engineered chondrocytes vs. control chondrocytes, assessed by life imaging and nano-indentation.
Reinforced 3D printed collagen-based scaffolds for articular joint repair

INTRODUCTION: Damage to articular cartilage does not heal readily, and often affects subchondral bone resulting in osteoarthritis. The complex layered composition of the cartilage-bone interface suggests multi-layered scaffolds will be required to ensure successful regeneration. To this end, this study used 3D-printed polymer frameworks to reinforce previously developed collagen scaffolds \cite{1,2}. Young’s modulus of the reinforcing 3D printed frameworks could be tuned to match cartilage, thus avoiding abrasiveness and producing a porous reinforced collagen scaffold for osteochondral repair.

METHODS: A biodegradable polymer was used to 3D-print (Biobot1, Allevi, USA) five different mesh designs with distinct pore architectures*. The stiffness (Young’s modulus) of the meshes was assessed using uniaxial compression testing (Zwick Roell Z005). Collagen-hyaluronic acid and -nanohydroxyapatite (CHyA, CnHA) slurries were incorporated into these meshes and freeze-dried, creating reinforced composite scaffolds. Microarchitecture was assessed by toluidine blue staining and SEM. Mesenchymal stem cells (MSCs) were used to assess the chondrogenic capacity of reinforced CHyA, via sulphated-glycosaminoglycan (sGAG) assay (Blyscan™).

RESULTS & DISCUSSION: The compressive moduli of the five mesh designs ranged from 0.7 to 17 MPa. The softest design (D5) lies in the range of articular cartilage and was used to reinforce the CHyA for chondrogenesis studies, while CnHA was incorporated into the stiffest design (D1) for future studies on osteogenesis. Both CHyA and CnHA scaffolds maintained high porosity in the meshes. GAG deposition in the reinforced CHyA was similar to that observed in non-reinforced control scaffolds.

CONCLUSIONS: Multi-layered reinforced scaffolds with mechanical properties suitable for osteochondral repair were created using 3D printing. Reinforcement was successful and did not affect porosity, which is crucial to achieve sufficient cell infiltration. Cartilage regeneration remains a significant challenge in tissue engineering, as biomaterial scaffolds needs to mechanically strong with a composition that can promote chondrogenesis. The composite scaffolds presented here build on success of previously CHyA scaffolds, which combined with 3D printing allows for their application to larger osteochondral defects.

INTRODUCTION: High throughput (HT) screening is an important process in pharmaceutical drug discovery and R&D. One crucial issue for in vivo-like cell behavior is the mechanical property (stiffness) of the 3D micro-environment. Our aim was to develop a screening platform with human primary cancer cells embedded in alginate-based hydrogel beads with different E-moduli.

MATERIALS & METHODS: Alginates at different concentrations and compositions were used to produce nanoliter-reactors (NLRs), suitable for microtissue (MT) growth and HT analysis. ZL55 cells (mesothelioma), encapsulated in NLRs (Ø=200 µm) formed MTs and remained viable up to 14 days. MTs grown in NLRs with higher E-modulus were smaller compared to those cultured in lower E-modulus NLRs but showed a higher metabolic activity (Ki-67-staining, PrestoBlue). Moreover, NLR stiffness seemed to have an influence on MTs’ morphology resulting in round- or oval-shaped MTs in high-stiffness and low-stiffness NLRs, respectively. Podoplanin gene expression increased with increasing alginate bead stiffness, while gene expression of mesothelin and survivin seemed not to correlate with stiffness changes. In order to automate NLR analysis, ZL55 cells were cultured for 14 days in NLRs and then stained with Nile Red to be sorted, according to their biomass, by flow cytometry using a COPAS BioSorter. Sorting procedure did not influence MT viability, a prerequisite for further drug testing. Alginate-free MTs revealed high resistance of ZL55 to cytostatic drugs, such as Taxol, Doxorubicin and Cisplatin. Sorted NLRs will be treated similarly to detect alginate’s influence. The final goal will be the generation of clonal patient derived cell lines which then can find application for personalized drugs screening as wells as cancer cell models.

RESULTS & DISCUSSION: As initial proof-of-concept, human primary mesothelioma cells, SDM81, were successfully encapsulated in NLRs made of different alginates. Although primary cells are more sensitive compared to cell line, cells were viable and grew up to 14 days in culture, demonstrating the high potential of the NLR technology for the cultivation and analysis of primary cells.

INTRODUCTION: Administration of Extracellular Vesicles (EVs) from mesenchymal stem cells (MSCs) is a promising nanotherapy for cardiac repair after myocardial infarction (MI), based on their immunomodulatory, regenerative, and pro-angiogenic capabilities. However, the optimal EV delivery strategy remains undetermined. We tested the use of biocompatible 3D-engineered cardiac scaffolds as an efficient support for local administration of EVs.

METHODS: EVs from porcine cardiac adipose tissue-derived MSCs (cATMSCs) were purified by size-exclusion chromatography (SEC) and checked for immunomodulation and recruitment capabilities towards allogeneic PBMCs and pro-regenerative cells, respectively. At the same time, EVs were fluorescently labelled for tracking and retention analysis after administration within a peptide hydrogel into cardiac scaffolds, generated by decellularization of healthy cardiac tissue.

RESULTS & DISCUSSION: EVs from porcine cATMSCs reduced allogeneic polyclonal proliferation and pro-inflammatory cytokines production (IFNγ, TNFα, IL12p40), and recruited pro-regenerative cells, including progenitor endothelial cells and allogeneic MSCs. These EVs were successfully retained by two different decellularized scaffolds engineered from cardiac tissues and peptidic hydrogel, with preserved structures and no immunoreactivity.

CONCLUSIONS: These data indicate that 3D-engineered cardiac scaffolds may effectively elicit myocardial local delivery of multifunctional cATMSC-EVs. Administration of EVs using a scaffold may be envisaged as cell-free off-the-shelf product for tissue repair, increasing the local EV dosage and generating a bioactive niche for cell migration and regeneration.

INTRODUCTION: Skin wound healing requires the recruitment and activity of different cell types, such as native immune response cells, endothelial progenitors, keratinocytes, and fibroblasts. Wound treated with Platelet Lysate (PL) gel recovered more quickly in all patients, leading to a reduction of hospital stay and of the related cost. Silk sericin (SS) is a globular and water-soluble protein with a molecular weight up to 200 kDa that, together with fibroin, constitutes the silk cocoon. The treatment of wounds should remove exudate, if present, in order to prevent infections. For this reason, to date, wounds are often treated with dressings based on alginate, which has excellent biocompatibility and ability to adsorb exudate.

METHODS: Sericin (SS), alginate (Alg) and PL were solubilized in distilled water and cast into freeze-dried molds. In vitro tests were performed to quantify the growth factor release from sponge/PL membrane by ELISA kit, the cytotoxicity of membrane and the capability of SS and PL alone or in combination, to induce proliferation and protective effects against oxidative stress. For all this analyses we used bone marrow stromal cells (BMSCs) and human fibroblast (hFB). We also tested the in vivo efficacy of our membranes in an excisional wound healing mouse model. The animals were sacrificed at different times (3, 7, 14 and 21 days) and a histological investigation was performed.

RESULTS & DISCUSSION: In vitro results indicated that the transformation of membrane into a gel take place in 48h with a burst of factor release. The presence of SS contributes and support the effect of PL by controlling the release of growing factors. The in vitro experiments showed a key role of the PL as a good inductor of cell proliferation and protector from oxidative stress condition and the SS a good modulator of its release. To be more sure of our hypothesis derived from in vitro experimental data, a wide study in vivo in mouse skin regeneration model was performed. This in vivo analyses showed how the membrane containing PL led to a faster regeneration of the skin respect to the control one (Alg:SS). We observed an inflammation phase occurred faster in treated lesion due to the presence of PL, that lead to a granulation tissue formation and subsequent collagen deposition and reepithelization and neovascularization. In control lesion we notice a non-complete resolution of the healing process.

CONCLUSIONS: This work propose a handle membrane composed of biomaterial (alginate and sericin) that are biocompatible and have particular mechanical properties, in association with a powerful inductor of cell activation that lead to complete skin regeneration. The SS contribute and support the effect of PL by its controlled release into the lesion.
Endothelial regeneration in coronary arteries from functionalized 3D printed poly-l-lactic acid bioresorbable stent

INTRODUCTION: Bioresorbable stents (BRS) are designed to overcome perceived limitations of drug-eluting stents (DES) by providing temporary support to the vessel wall. Herein, we developed bioactive 3D printed BRS with enhanced mechanical properties by solvent-cast direct-write technique to overcome atherosclerosis whilst regenerating coronary arteries endothelium.

METHODS: 3D printed stents were obtained with a modified fused deposition modelling (FDM) 3D printer (BCN 3D+, BCN 3D technologies). The ink was a solution of poly-l-lactic acid (PLLA, PL65, Purasorb) in chloroform (3.7%v/v) dissolved in a speed mixer (FlackTek). REDV and YIGSR peptides were synthesized by solid-phase and covalently attached to the surface using EDC/NHS. Mechanical assays consisting of crimping the stent and expansion into a silicone tube and average breaking pressure were carried out. HUVEC adhesion and proliferation was characterized by immunofluorescence. HUVEC migration was performed through a wound-healing assay. Thrombogenicity was tested into a prefusion chamber with volunteer donor’s blood. Statistical analysis was realised by non-parametric Mann-Whitney U-test using Minitab software.

RESULTS & DISCUSSION: PLLA biodegradable stents of 3 mm diameter and between 15-20 mm length were obtained by means of a modified FDM 3D printer with different peaks (Figure 1). Actual commercial BRS have struts of 130 μm diameter, while in our study we were able to obtain values down to 80 μm. Thermal treatment eliminated chloroform residues from fabricated stents and increased crystallinity up to 28.7 % compared to non-treated stents.

CONCLUSIONS: The fabrication of a biactive biodegradable stent by 3D printing was successfully achieved by SC-DW with a self-modified FDM. Biological assays confirmed that 3D printed BRS by SC-DW were not cytotoxic and functionalization enhanced endothelial regeneration.

Figure 1: (Left) 3D printed PLLA stents: (a) peak number (n=5); (b) different stents n= 7,10, 15, 20. Average breaking pressure was between 15-17 atm and a good stent deployment was observed into the simulated artery. Biological tests confirmed that 3D printed stents were not cytotoxic independently of the number of peaks. Finally, functionalization enhanced HUVEC migration and did not increase thrombogenicity. Figure 2: (Right) Thrombogenicity test on stents with different strut diameter.

INTRODUCTION: Microbes colonizing the gut (microbiota) can alter brain physiology and be involved in neurodegeneration [1]. The ERC “MINERVA” project aims at developing the first engineered organ-on-a-chip platform to simulate in vitro the key features of the microbiota-gut-brain axis in physiological and pathological scenarios. Herein, we set up an innovative 3D brain cell model potentially suitable to simulate the key hallmarks of Alzheimer’s disease (AD) in the brain compartment of the MINERVA device [2].

METHODS: We cultured amyloid precursor protein (APP)-Swedish mutant H4 cells in both collagen/poly(ethylene glycol) (PEG) [3] and collagen/hyaluronic acid (HA) gels. We tested two conditions: a) embedding in hydrogels; b) plating in culture plates and covering by a layer of gel. We varied hydrogel thickness and studied the influence of cell number and volume ratio between medium (or cell suspension) and polymer components on collagen fibrillogenesis by measuring the optical density at 400 nm. We analyzed the samples by transmission electron microscopy (TEM). We varied gel thickness and measured cell metabolic activity with time by MTS assay after embedding 3.125·10⁵ cells/cm² or plating 2.34·10⁴ cells/cm². For the best conditions, we examined the trapping of β-amyloid peptide (Aβ) by confocal microscopy.

RESULTS & DISCUSSION: For all gels, the reduction in thickness from 5.1 to 1.25 mm did not hinder the gelling process, but influenced the lag time and fibril diameter. TEM confirmed a reduction in fibril diameter when decreasing the thickness. Cell metabolic activity was greater on day 10 for both culturing conditions. For covered cells, regardless of hydrogel composition, the greatest thicknesses led to the lowest metabolic activity. We performed immunofluorescence analyses on samples of 1.25- and 2.5-mm thick. Only for embedded cells, we detected a diffuse signal referable to Aβ.

CONCLUSIONS: Our 3D brain cell model is potentially suitable to recapitulate Aβ accumulation in vitro.

ACKNOWLEDGEMENTS: MINERVA project received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation program (grant agreement no.724734). We thank C. Maffeis for technical support.

INTRODUCTION: To recreate fully defined three-dimensional (3D) (stem) cell niches, hydrogels with bio-chemically and mechanically tailorable properties were developed. For this a major focus was on the localized presentation or delivery of growth factors and controlling of integrin binding sites. Due to the lack of standardized procedures for the evaluation of extracellular matrix (ECM) components in 3D cultures, limited data on the remodeling of engineered cellular microenvironments and according consequences on cell functions are available. To evaluate ECM proteins and their function in the establishment of 3D tissue models, we have employed label-free proteomics, RNA-sequencing and co-cultures of endothelial cells with fibronectin-depleted human bone marrow mesenchymal stromal cells (hMSCs).

METHODS: Poly(ethylene glycol) hydrogels (PEG) were optimized for 3D cultures with hMSCs or co-cultures of hMSCs with human umbilical vascular endothelial cells (HUVECs). 3D tissue constructs were cultured in presence or absence of supportive growth factors and evaluated by 1) fluorescence or electron microscopy, 2) harvested by FACS sorting for RNA sequencing, or 3) digested by trypsin for the harvesting of cells and ECM proteins and their processing for label-free proteomics. For fibronectin-depletion hMSCs were treated with siRNA.

RESULTS & DISCUSSION: PEG hydrogels with low stiffness allowed hMSC to spread and deposit various ECM components as shown by immune stains and label-free proteomics. PEG hydrogels allowed temporary spreading of HUVECs but could not support their long-term survival. In contrast co-cultures of HUVECs and hMSCs formed stable 3D vascular networks with morphologies similar to natural capillaries (including vascular lumen). As shown by RNS-sequencing, MSCs derived from co-cultures exhibited a shift in ECM expression when compared to hMSCs from monocultures. When their fibronectin expression was suppressed hMSCs could only partially spread even in the presence of RGD. Additionally, in absence of fibronectin the secretion of all other ECM components was almost completely abrogated. Furthermore, the formation of vascular structures was completely suppressed.

CONCLUSIONS: Our data indicate that in 3D cultures cell-secreted ECM components play a crucial role. This becomes best visible in cultures, where the fibronectin deposition in MSCs is inhibited, resulting in the abrogation of ECM deposition and cell spreading. In co-cultures of hMSCs with HUVECs, hMSCs were shown to play a guiding function in the formation of vascular structures, since vessel formation was critically dependent on MSC-derived matrix components. Taken together, 3D tissue formation in synthetic substrates is significantly modulated by cell-secreted ECM components. Understanding the role of this ECM will thus be crucial for the engineering and manipulation of stem cell niches.

INTRODUCTION: Cancer metastasis is a multistep process during which multiple players establish competitive mechanisms whereby cancer cells experience pro- and anti-metastatic effects. Available in-vitro models are limited for the study of complex interactions, due to simplification as compared to physiological tissues. Exploiting our already developed microfluidic model, we aim at replicating the so called early metastatic niche (EMN), characterized by the heterotypic cross-talk between platelets, neutrophils, endothelial cells (HUVECs) and breast Cancer Cells (bCCs), which represents a crucial event for metastatic progression.

METHODS: Microfluidic vascularized models have been generated by co-culturing fibroblasts and HUVECs embedded in a fibrin gel for 4 days. To investigate the role of platelets and neutrophils in breast cancer cells (bCCs) extravasation, we co-cultured bCCs, platelets and neutrophils (isolated from human buffycoat) and after 24 h we injected the cells suspension into the perfusable vessels. We measured bCCs adhesion to HUVECs, extravasation and migration by confocal imaging. We also investigated the effects of a clinically approved anti-platelet drug (αIIbβ3 inhibitor Eptifibatide, 15 µg/ml) on each component of the EMN and the interplay among these components.

RESULTS & DISCUSSION: bCCs extravasation significantly increased in presence of platelets and neutrophils as compared to control conditions (49.99±3.39% vs. 22.66±4.75%, p<0.001). Regarding the interactions between EMN components, we saw that neutrophils shifted bCCs towards a rounded shape suggesting a less aggressive phenotype, while the simultaneous presence of neutrophils, platelets and endothelial cells partly reversed the effect. The addition of αIIbβ3 inhibitor significantly reduced the number of extravasated bCCs (p<0.001), reducing platelet activation (αIIbβ3) and decreasing SrcY416, FAKY397, (VE)-cadherinY658 phosphorylation, leading to HUVEC junction tightening which could partly explain the reduction in bCCs extravasation.

CONCLUSIONS: Exploiting our approach, we demonstrated how concomitant interactions with several niche components modified the behavior of other cell populations as compared to the effects of the single interactions. As an example, neutrophils acted with a context-dependent behavior, increasing or decreasing bCC aggressiveness when alone or in co-culture with other EMN components. Furthermore, we showed that αIIbβ3 inhibitor decreased bCCs extravasation through concurrent mechanisms acting on different EMN components, highlighting how a clinically approved antiaggregant can contribute to an anti-metastatic effect.

INTRODUCTION: Despite medical advances, myocardial infarction (MI) remains among the main causes of death in western countries. Electroconductive biomaterial scaffolds and electrical stimulation can improve the differentiation of progenitor stem cell sources into cardiomyocytes and the maturation of cardiac engineered organoids. In this study, we aim to process an electroconductive scaffold with optimized features for tissue engineering applications.

METHODS: Poly (3,4-ethylenedioxy thiophene):polystyrenesulfonate (PEDOT:PSS) was functionalized with stabilizing molecules, doped with 4-dodecylbenzenesulfonic acid (DBSA) and processed into films or three-dimensional (3D) scaffolds using spin-coating and freeze-drying respectively. Crosslinking investigations were performed using X-ray photoelectron spectroscopy (XPS) and Fourier transform infrared (FT-IR) spectroscopy. In parallel, 3D constructs were manufactured and characterised with scanning electron microscopy (SEM), ethanol intrusion measurements uniaxial compression testing, and 2-point probe experiments. Finally, direct and indirect cytotoxicity assays were performed to evaluate biocompatibility.

RESULTS & DISCUSSION: XPS and FTIR demonstrated a unique crosslinking interaction between PEDOT:PSS and the novel molecules. Optimised freeze-drying parameters resulted in highly porous scaffolds with tunable dimensions and aligned or isotropic micro-architecture. Scaffolds can be needle injected into aqueous environments and afterwards gain their original form. Theses scaffolds possess conductivity and mechanical properties in ranges that match that of the myocardium to induce myogenic differentiation.

CONCLUSIONS: We developed a novel functionalized PEDOT:PSS scaffold that exhibits high porosity, tunable morphology, memory shape and low temperature processing,

INTRODUCTION: Tissue engineering scaffolds are designed to create an environment that encourages tissue growth. However, many of the same processes and cells involved in tissue healing are associated with tumor progression, including immune cells. Cancer immunotherapy attempts to reverse tumor escape from immune clearance, but is currently unknown whether a pro-regenerative scaffold immune environment affects immunotherapy responses.

METHODS: B16-F10 melanoma cells were co-injected with decellularized urinary bladder matrix (UBM) particles in C57BL/6 mice. Tumor immune infiltrate was characterized by flow cytometry and histology. Cancer immunotherapy response in the UBM microenvironment was interrogated by delivering systemic anti-PD-1 (programmed cell death protein 1) or isotype controls 8 days after cancer injection with UBM. Mice that survived the initial inoculation were rechallenged with B16-F10 and MC38 cells.

RESULTS & DISCUSSION: The UBM biologic scaffold microenvironment inhibited B16-F10 melanoma formation synergistically with anti-PD-treatment. B16-F10 cells were cleared by the combination of UBM and immunotherapy in approximately 20% of mice. These mice were also protected on rechallenge with B16-F10, but were not protected against the unrelated colon cancer cell line MC38 suggesting B16-F10 antigen specific immune recognition. The UBM microenvironment differed substantially from control melanoma tumors. T cell infiltration increased nearly 3-fold with UBM compared to Saline, as did proportions of natural killer (NK) and NKT cells. Histologic staining revealed that the majority of T cells in the UBM microenvironment were CD4+ T helper cells. Tumor growth inhibition with UBM was dependent on CD4+ T helper cells. Tumors readily grew in Rag1⁻/⁻ mice that lack mature T cells and B cells. However, adoptively transferring CD4+ T cells into Rag1⁻/⁻ mice rescued tumor inhibition to a similar extent as wild type mice.

CONCLUSIONS: UBM attracts immune cells and creates a unique environment that synergizes with checkpoint blockade immunotherapy to further activate responding T cells. As clinical administration of checkpoint immunotherapy is evolving, pro-healing biologic scaffolds may provide both a vehicle for tissue reconstruction and a mechanism to prime the local immune environment for optimal drug efficacy.
Evaluation of polysaccharide based sealants for soft tissue reconstruction
M. Schnabelrauch¹, K. Wagner¹, J. Becher¹, A. Berg¹, S. Voigt², A. Enkelmann², G. Schneider²
Presenting Author: Matthias Schnabelrauch, ms@innovent-jena.de
¹INNOVENT e. V., Biomaterials Department, Jena, Germany ²Jena University Hospital, Department of Otorhinolaryngology, Jena, Germany

INTRODUCTION: The high incidence of soft tissue damage due to trauma or tumor removal asks for new solutions to reconstruct those defects overcoming current limitations. Adhesives able to attach on wet surfaces and bind tissues together seems to be an alternative to suturing and stapling techniques. In this context, we evaluated cross-linkable polysaccharide hydrogel compositions as sealants in soft tissue reconstruction.

METHODS: Crosslinkable units (dialdehyde, carboxymethyl, methacryloyl groups) were introduced into the polysaccharides dextran, levan, chitosan, and hyaluronan using published procedures [1]. The prepared derivatives have been structurally characterized by common analytical techniques. Hydrogel formation was initiated by azomethine-, amide-, or radical polymerization-type crosslinking reactions. The adhesion strength of bonded sealants was determined under defined conditions using a texture analyzer TA-XT2i. In first bonding experiments float glass samples were used followed by substrates from fresh meat (6 hours after slaughter) from different pork tissue samples (mucosa membranes, muscle tissue). In vitro degradation of the sealants was studied gravimetrically in simulated body fluid (SBF) medium at 37°C for defined time intervals. The in vitro cytocompatibility was tested with fibroblast cells using commercial WST-1® and LDH assays.

RESULTS & DISCUSSION: Stable hydrogels could be prepared by azomethine-type reaction of chitosan with dextran or hyaluronan dialdehydes and also amide-type reaction of carboxymethyl chitosan after crosslinking with a water-soluble carbodiimide. Hydrogels of levan, dextran and hyaluronan methacrylates can be obtained using conventional photoinitiators. In all cases the curing times of gel formation were below 30 min. The hydrogels showed an excellent in vitro cytocompatibility and a gradual degradability dependent on the type of polysaccharide and the degree of introduced functional group varying from several days to months. Dry bonding of float glass substrates gave highest values for tensile shear strengths in the methacrylate (150-300 kPa) followed by the azomethine (70-80 kPa) and the amide series (20 kPa). Interestingly, under wet bonding conditions, there was only a very slight decrease of tensile shear strengths found for both the azomethine- and the amide-type sealants. In bonding experiments with fresh meat slices an excellent adhesion of the sealant to wet tissue was found and for the azomethine-type sealant tensile shear strengths of up to 1.7 kPa compared to 1.2 kPa for commercial fibrin sealants were received. Whereas bonding of mucosal tissue was rather difficult to achieve, satisfied results could be obtained in bonding tests with pork muscle tissue.

CONCLUSIONS: Chitosan in combination with polysaccharide aldehydes forms rapidly curable, highly cytocompatible, degradable hydrogel sealants with optimal adhesion on wet tissue surfaces and tensile shear strengths for soft tissue in the same range as conventional fibrin glue.

INTRODUCTION: Meniscal injuries are often associated with an active lifestyle, and the damage of this tissue renders young patients at higher risk of undergoing meniscal surgery and in time evolving in osteoarthritis (OA). 3D bioprinting has shown great potential in tissue engineering allowing to fabricate customized high-resolution structures starting from imaging data of the patient. The novel technique of simultaneously printing cells embedded into an appropriate biomaterial may be able to produce biological substitutes with enhanced efficiency in tissue regeneration and functional restoration. In this light, an early experience is presented on the production of a custom-made cell-laden collagen-based human meniscus.

METHODS: the 3D model of bioengineered meniscus was based on a Magnetic Resonance Imaging (MRI) scanning, processed using the dedicated software “Mimics” (Materialise, Leuven, BE). Lifelink® 200 purified, highly concentrated Type I Collagen bioink (Advanced Biomatrix, USA) with embedded human Mesenchymal Stem Cells (hMSCs) (40x10⁶) was printed by means of a 3D Discovery bioprinter (RegenHu, CH). The chosen 3D Discovery printing tool was a microvalve-based inkjet printhead. The printing process was directly performed in culture medium in a sterile Petri dish, kept at 37°C. After printing, cell viability was evaluated by Live & Dead assay.

RESULTS & DISCUSSION: The selected bioink presented good printability and shape-fidelity, allowing the fabricated tissue, obtained by means of a microvalve-based inkjet dispensing technique, to mimic the anatomical model morphology as can be seen in Fig. 1. Moreover, this “cell-friendly” technology allowed hMSCs included into the bioink to be homogeneously distributed within the construct with high viability (95%) for up to 28 days in culture.

CONCLUSIONS: The prototype that we realized, shows the biologic potential of 3D bioprinting technology to provide an anatomically shaped patient-specific construct with viable cells embedded in a biocompatible material. It also sets the starting point for future developments of custom-made tissue-engineered structures toward the optimization of implants to replace damaged tissues.

INTRODUCTION: This project aims to determine whether nasal chondrocytes can be considered as an autologous cell source for cell therapy of disc degeneration by comparing them to MSCs and articular chondrocytes, two cells sources used in phase two clinical trials at the moment.

METHODS: Cells are cultured in in vitro micro -mass culture conditions mimicking facets of a degenerated intervertebral disc, such as hypoxia, low glucose, inflammation, and acidity. The production of the extra cellular matrix is evaluated using immunohistochemistry, quantitative real time PCR, and biochemical analysis.

RESULTS & DISCUSSION: Our data demonstrate MSCs, ACs, and NCs have a similar GAG and Collagen 2 production in response to in vitro conditions simulating singular facets of the IVD environment and the addition of TGFβ1. However, NCs synthesis more of these ECM components than MSCs or ACs when cultured in the same conditions without the addition of the growth factor. Furthermore, growth factor primed NCs maintain an exceeding production of GAG and Collagen 2 compared to both growth factor primed MSCs and ACs in harsher conditions, which combine different characteristics of the degenerated IVD environment. Interestingly, the indifference of ECM production of NCs in response to inflammation factors cannot be linked to the absence of gene expression of the respective receptors. Moreover, NCs as the only cell sources display gene expression of the transcription factor FoxF1, a marker for nucleus pulposus cells.

CONCLUSIONS: In summary, NCs are more similar to nucleus pulposus cells than MSCs and ACs, as they can better produce ECM in an in vitro IVD environment and express the nucleus pulposus marker FoxF1. These findings encourage the assessment that employing NCs in a cell therapy treatment of degenerated disc disease could promote new matrix production in the disc, which could inhibit or delay further disc height loss if not even lead to disc height gain.
Marine polysaccharide-based bioartificial pancreas for type-1 diabetes
M.L. Amin¹, D. Mawad¹, C.C. Sorrell¹

INTRODUCTION: Destruction of pancreatic islets by autoactivated immune system leads to type-1 diabetes, which affects ~90,000 children every year [1,2]. Implanted islets embedded in a suitable carrier as a bioartificial pancreas are considered to be a potential alternative to native islets. Marine sulfated polysaccharides, fucoidan and carrageenans (λ-, ι-, and κ-), exhibit characteristics similar to those of physiological polysaccharides and they can bind with growth factors and ligands [3]. The aim of the present work was to develop an immunomodulatory construct by copolymerizing these polysaccharides with polyvinyl alcohol (PVA), thus imparting biological functions to the resultant hydrogels.

METHODS: PVA, fucoidan, and three commercially available carrageenans were methacrylated (MA) and their cytotoxicities were tested using fibroblast L929 cells. The hydrogel disks (9 or 19 wt% PVA-MA + 1 wt% polysaccharide-MA) were fabricated using 0.025 wt% Irgacure 2959 photoinitiator and they were characterized by mass loss, swelling, and polysaccharide release by dimethylmethylene blue (DMMB) assay (up to 7 days). Further, MIN6 cells were encapsulated in hydrogels and cell viabilities were assessed by live/dead assay. Cellular ATP level and insulin secretion also were evaluated progressively over a period of 32 days. Finally, the cell-containing hydrogels were exposed to a medium containing inflammatory cytokines (IL-1β, TNF-α, and IFN-γ) in order to examine the immunomodulatory characteristics of the hydrogels.

RESULTS & DISCUSSION: The polymers were found to be cytocompatible (>94% cell viability) by the cell growth inhibition assay. The addition of the polysaccharides did not cause considerable changes in mass loss and swelling of the hydrogels. The DMMB assay revealed that >50% of the polysaccharides were covalently bound to the PVA. Significantly, the number of sulfate groups in each polysaccharide repeating units correlated directly with the viability of the encapsulated MIN6 cells. Hence, >95% cell viability (32 days) was observed for PVA-fucoidan and PVA-λ-carrageenan hydrogels, both of which contain the maximum of three sulfate groups. The encapsulated cells formed islet-like spheroids inside the hydrogels and had consistent ATP level. The glucose-stimulated insulin secretion assay revealed that the cells retained their insulin-secretion profile. Further, hydrogels containing fucoidan and λ-carrageenan were observed to protect the cells from inflammatory cytokine-induced apoptosis.

CONCLUSIONS: The present work reports successful design of a bioartificial pancreas, revealing the importance of maximizing the number of polysaccharide sulfate groups. Consequently, fucoidan and λ-carrageenan in PVA-based hydrogels can be leveraged to enhance islet survival and functionality, indicating that these hydrogels can be used for in vivo islet implantation for the treatment of type-1 diabetes.

INTRODUCTION: Vascular tissue engineering requires the implants which avert the restenosis, thrombosis and immunological reactions and must withstand physiological pressures without any leakage [1]. Flow induced physiologic system plays a pivotal role in cell alignment and vessels maturation [2]. This study explores the influence of mechanical stimulation on the 3D printed co-culture system consisting of Endothelial cells (EC) and Mesenchymal stem cells (MSC) on the vessel maturation and efficacy of the graft.

METHODS: Alginate-Gelatin bioink with EC and MSC’s were prepared and-a tubular CAD design is 3D printed. Medium was changed for every two days during the static culture of the 3D printed scaffolds. To study the effect of physiological pulsatile flow stimulation on the 3D printed scaffolds a bioreaction chamber was 3D printed using an FDM 3D printer with extensions to support perfusion. FDA/PI, Alamar Blue, Picogreen, SEM, Mechanical testing and IHC were performed at week 1 and week 3 for both static and dynamic conditions.

RESULTS & DISCUSSION: The surface morphology and structural integrity of the scaffolds were observed using Scanning Electron Microscopy (SEM) and adherence of cells on the top layer was evidenced. Live dead staining shows better biocompatibility and proliferation in dynamic conditions. The custom made bioreactor to simulate the physiological condition of blood vessel did not show any a toxic effect. Dynamic culture conditions allow the cells to mature and express genes for the vascular tissues such as CD31, VEGFR and vWF. Significant increase in mechanical strength and expression of angiogenic markers were observed in 3D printed vascular grafts cultured under dynamic conditions with flow stimulation when compared with static conditions.

CONCLUSIONS: ECs and MSCs are maturing together in dynamic conditions and are collectively responsible for increase in the mechanical strength of the vascular grafts. The mechanical stimulation provided externally is also contributing to the enhanced maturation of the coculture system. Vascular grafts fabricated and matured using these bioreactors have huge potential in vascular tissue engineering.

INTRODUCTION: Extracellular matrix (ECM) is a fibrous network produced by cells that has been employed in tissue engineering endeavors. The objective of this work is to improve the mechanical properties of decellularized pericardial ECM by reinforcing it with poly(propylene fumarate) (PPF).

METHODS: PPF was synthesized and diluted with diethyl fumarate (DEF) at a PPF:DEF ratio of 2:1.1,2 Bovine pericardium was freshly isolated and used as is (nECM), decellularized (dECM), or decellularized, dehydrated with serial dilutions of ethanol (20%, 40%, 60%, 80%, and 100%), coated with the 2:1 PPF:DEF solution, and crosslinked in the presence BAPO (dECM+PPF) (Fig 1A). The aforementioned tissue decellularization utilized a previously published protocol.3 Half of the samples were digested in collagenase for four hours to simulate in vivo degradation. The samples were tensile tested to quantify tensile properties (Fig 1B) and suture retention strength (Fig 1C).

RESULTS & DISCUSSION: The toughness of both native and decellularized pericardium (nECM and dECM), decreases significantly (p<0.005) with collagenase digestion, while the pericardium that has been reinforced with PPF (dECM+PPF) does not experience a significant change (p>0.05). The coupling of pericardium with PPF prevents a loss of toughness in the pericardium when exposed to collagenase. Similarly, the maximum suture retention force after collagenase degradation of pericardium reinforced with PPF (dECM+PPF) is significantly higher than that of the decellularized pericardium (dECM). The application of PPF reduces the detrimental effects of collagenase on the suture retention strength of the pericardium.

CONCLUSIONS: PPF reinforcement methods improve the tensile behavior and suture retention of pericardial ECM, despite collagenase degradation for applications in small diameter vascular grafts. These trends will be utilized in future research to understand the cell response in the biohybrid vascular grafts.

INTRODUCTION: Knee is the second most common site of osteonecrosis after femoral head with very demanding management, often requiring invasive surgical procedures. Novel material formulations, easier to use and combinable with biological adjuvant, might offer new therapeutic possibilities, but the relevant blank in preclinical models makes the evaluation of innovative therapy difficult. Aim of our work was to assess the osteogenic potential of injectable calcium phosphate pastes (biomimetically precipitated nano-size HA in Recombinant Collagen-like Peptide solution), and to study the set-up of a preclinical model of knee osteonecrosis, both in vitro and in vivo.

METHODS: In vitro study: Bone marrow human mesenchymal stem cells were co-cultured with two calcium phosphate formulations for 2 weeks and tested for viability and osteogenic differentiation. An in vitro culture model was set up with rabbit femoral condyles for 4 weeks to compare the effectiveness and feasibility of two methods for necrosis induction: ethanol injection and cycles of freezing/thawing, evaluated with viability assay, RNA yield and histology. In vivo study: a rabbit model of knee osteonecrosis was set up via injection of absolute ethanol. After 4 weeks, rabbits were randomly treated with the calcium phosphate material resulting more suitable after in vitro culture, with and without autologous bone marrow concentrate. After 8 weeks outcomes were evaluated histologically.

RESULTS & DISCUSSION: In vitro study: Bone marrow human mesenchymal stem cells cultures showed that both materials tested stimulate osteogenic differentiation, increasing the expression of RUNX2, COL1A1, VEGF. As for osteonecrosis induction protocols, both treatments induced a sharp drop of viability without recovery over time in comparison to control group, reduction in RNA yield with poorer A260/280 and A260/230 and RNA degradation, and histological signs of necrosis. In vivo study: After 8 weeks, untreated group showed histopathological signs of bone necrosis, with empty lacunae and signs of substitution of normal bone marrow with adipose tissue. Histology in treated groups highlighted high bone metabolic activity, with presence of osteoblasts along trabeculae, lacunae generally filled with osteocytes and reactive bone marrow.

CONCLUSIONS: Results obtained from the study proved that the materials tested can be suitable for application in regenerative medicine protocols. The feasibility of the in vitro model adopted open up the possibility to use such a long term bone culture for preliminary therapy evaluations and its reliability allowed to successfully set up an in vivo model of knee osteonecrosis, never described in literature.

INTRODUCTION: Mesenchymal stromal cells (MSCs) have great potential in cell-based therapies for restoring structure and function of many tissues including neuromuscular tissues. While human adipose- (ADSC) and umbilical cord-derived (ucMSCs) were shown to differentiate into a striated muscle phenotype using horse serum (HS) [1-3], to date bone marrow-derived MSCs (bmMSCs) have only been shown to differentiate into striated muscle using 5-azacytidine, a chemotherapeutic DNA-methylation inhibitor [4-5], or a complex mix of cytokines including bFGF, PDGF, forskolin and neuregulin, followed by transfection with notch intracellular domain [6]. However, neither of these approaches is clinically feasible. Hence, this study investigated the effects of a GMP-compliant medium on the differentiation of bmMSCs into a neuro-muscular phenotype vs. the standard HS protocol commonly used to differentiate ADSCs, ucMSCs and C2C12 cells.

METHODS: bmMSCs were expanded in DMEM, 5% human plasma (P) and platelet lysate (PL). At P2 cells were placed in 8-well chamber slides or 12-well plates (3000 cells/cm²) and further cultured in P/PL medium or 5% HS, 0.1µM dexamethasone, and 50µM hydrocortisone for 14 days. Expression of myogenic and neurogenic markers were quantified (ddPCR and immunofluorescence).

RESULTS & DISCUSSION: P/PL expansion (day 0) followed by treatment of bmMSCs with P/PL or HS (day 14) led to essentially zero expression of myogenic markers MyoD, MyoG, Myf5, and ACTA1 and low Desmin expression (Table I). P/PL expansion led to a high baseline expression of Coronin1b, vs. SJCR10 cells or mature skeletal muscle, which was not further increased with P/PL or HS. Yet P/PL led to a significant increase in GAP43 expression vs. HS (day 14). Moreover, the protein expression of GAP43 and Desmin was significantly increased by both P/PL and HS (Fig. 1, day 14 vs. day 0).

CONCLUSIONS: Adult bmMSCs expanded in GMP-compliant medium do not undergo myogenesis at day 14 using P/PL or the commonly used HS method to differentiate other MSC types. However, P/PL, and to a lesser extent HS, potentially stimulated a neuron-like phenotype.

INTRODUCTION: In vitro expansion of tenocytes leads to phenotypic drift and loss of function [1]. Different microenvironmental cues has been employed to maintain the phenotype of tenocytes [2, 3]. Herein, in this study we venture to assess the synergistic effect of aligned Biosyn® fibres, macromolecular crowding and TGFβ3 supplementation in tenogenic phenotypic maintenance.

METHODS: Human tendons were kindly provided from University Hospital Galway, after obtaining appropriate licenses, ethical approvals and patient consent. Afterwards, tenocytes were extracted using the migration method. To produce electrospun fibres, a 10 % w/v solution of Biosyn® in 1,1,1,3,3,3-Hexafluoro-2-propanol was prepared and supplied by a syringe pump at a flow rate of 20 μl/min. Aligned fibres were produced by electrospinning onto a collector covered with aluminium foil which was rotated at 3,000 rpm. SEM analysis was performed to visualise the fibres and to quantify fibre diameter. At passage 3 tenocytes were seeded onto the fibres and were supplemented with 5 ng/ml TGFβ3 and 50 μg/ml Carrageenan. Cell morphology was assessed using rhodamine/phalloidin staining. Cell proliferation and metabolic activity were assessed using Picogreen® and alamarBlue® assays. ECM synthesis and deposition were assessed using immunocytochemistry analysis. All experiments were performed at least in triplicate. MINITAB (version 16; Minitab, Inc.) was used for statistical analysis.

RESULTS & DISCUSSION: SEM analysis revealed fibre alignment with a range of diameter between 800-1600 nm. Cell morphology showed tenocyte arrangement to the direction of the fibres. Cell proliferation was significantly enhanced on cells seeded in fibres and supplemented with TGFβ3 and/or CR when added in serial fashion. Immunocytochemistry analysis demonstrated that human tenocytes seeded on aligned fibres and supplemented with TGFβ3 and CR at serial fashion increased synthesis and deposition of collagen type I, which is the major component of tendon ECM, as well as the tendon-specific ECM proteins collagen type III and V. In addition, collagen fibres were also aligned to the direction of the fibres mimicking collagen orientation in the tendon tissue.

CONCLUSIONS: Collectively, results suggest that the synergistic effect of surface alignment, MMC TGFβ3 can accelerate the formation of ECM-rich substitutes, which may stimulate tenogenic phenotype maintenance. Currently, further analysis for tendon specific genes is being conducted to validate our promising results.

INTRODUCTION: Cartilage damage is a highly observed clinical situation in orthopaedic treatments. Although there are traditional treatments known as autografting and allografting techniques, they have risk factors such as donor site morbidity, infections and immunogenic reactions [1,2]. Recently, studies have focused on tissue engineering applications as alternative methods to replace surgical procedures. In this study, it was aimed to fabricate bioactive Helix aspersa extract loaded chitosan scaffolds with slime and mucus incorporation and to investigate the composite structures in terms of physical, morphological and biological compatibility for bone-cartilage regeneration.

METHODS: Chitosan-slime and chitosan-mucus scaffolds were prepared with snail (Helix aspersa) secretions at different amounts (0.5%, 1% and 3%). Scaffolds were fabricated via lyophilization method. Morphology of scaffolds were determined by Scanning Electron Microscopy (SEM) and chemical composition by Fourier Transform Infrared Spectroscopy (FT-IR). In addition, swelling ratio test, open porosity determination, biodegradation test, biomechanical analysis (compression tests) and antimicrobial tests for five different strains were performed. In vitro bioactivity of chitosan-slime and chitosan-mucus scaffolds has been investigated with Saos-2 and SW 1353 proliferation. Osteogenic effect of extracts is investigated with ALP activity, osteocalcin secretion and biomineralization, whereas, chondrogenic potential of scaffolds is evaluated with GAG assay, hydroxyproline content and COMP assay.

RESULTS & DISCUSSION: As a result, scaffolds containing snail extracts have been produced as intended. As the extract incorporation in polymer matrix increased, the mechanical strength was enhanced, and biodegradation rate increased. However, swelling ratio of chitosan scaffolds decreased with extract incorporation. SEM images showed that the pore size of the scaffolds decreased with higher extract content when compared to control group. Furthermore, porosity of all scaffold groups was obtained above 80%. The antimicrobial tests indicated that snail extracts showed antimicrobial effect on two bacterial strains out of five.

CONCLUSIONS: The scaffolds which have produced for bone and cartilage provided antimicrobial characteristics as well as suitable morphological and mechanical properties.

ACKNOWLEDGEMENTS: The authors are greatful to Izmir Institute of Technology (Iztech) Biotechnology and Bioengineering Research and Application Center (IZTECH BIOMER) for antimicrobial tests and FT-IR analysis, Center for Material Research (IZTECH CMR) for SEM imaging.

INTRODUCTION: Human cornea is one of the most transplanted tissue worldwide, but faces intense shortage in donors. Gelatin-based hydrogels are commonly used in corneal tissue engineering, but they lack mechanical and thermal stability. It is hypothesized that gelatin can be reinforced by the addition of the protein crosslinking enzyme transglutaminase (Tgase) and polysaccharide gum acacia (GA), to obtain a novel hydrogel for corneal regeneration. Hydrogels will be assessed for biocompatibility using human adipose derived stem cells (ADSC) and 3D printing will be used to design moulds to form the implant.

METHODS: Hydrogels were prepared using 15% w/v of gelatin, 2.5% w/v Tgase and varying concentrations of GA (3, 2, 1, and 0.5% w/v). The time taken for solidification and gel thermal stability was measured at 37°C. Thin films of hydrogels were prepared in 24 well plates by drying them in 40°C overnight. 50,000 ADSCs seeded on rehydrated hydrogels and cultured for 48h. ADSCs cultured on the tissue culture plates acted as controls. Images of the cell were taken to assess biocompatibility. The gels were moulded into the shape of a corneal implant using 3D printed corneal moulds.

RESULTS & DISCUSSION: All the gels except the pure gelatin gel control were found to be thermally stable. 3% GA gels solidified fastest (18 mins) versus 0.5%GA which solidified in 25mins. Cells remained viable and gels were found to be biocompatible with ADSCs. Cells cultured on gels with 0.5%GA showed highest similarity to controls grown on tissue culture plates (Fig.1: a&b). Hydrogels containing 0.5%GA were chosen to be carried forward to be moulded in the shape of cornea. Blender was used to computationally design a 3D printed mould. After converting to STL format designs were printed on a Stratasys 3D ABS printer (Fig. 1 C). Moulds required treatment using acetone vapor exposure for smooth the printed surfaces. 0.5% GA hydrogels were set using the 3D printed moulds resulting in corneal bioimplants (Fig. 1d).

CONCLUSIONS: This study shows that gelatin hydrogels with transglutaminase and Gum acacia can be used to form hydrogels. These hydrogels are biocompatible to ADSCs. Using 3D modelling it is possible to design and 3D print moulds to set the hydrogels into a corneal implant morphology. Current studies are examining the differentiation of ADSCs into corneal keratocytes within this formulation and potential for 3D bioprinting cornea implants.

Figure 1: (a) ADSCs tissue culture plate monolayer culture was found to be morphologically similar to (b) ADSCs cultured on gels with 0.5%GA. (c) 3D printed corneal mould and (d) the gel with 0.5%GA shaped into cornea using the mould.

ACKNOWLEDGEMENTS: Financial support was received from RCSI Bahrain.
Production and analysis of bioprinted skeletal muscle tissue for drug development

Novel treatments against muscle-related diseases are becoming important due to the growth of the aging population. Currently, no robust medium throughput in vitro skeletal muscle model exists to assess drug effects on muscle contraction. Muscle functionality strongly depends on the three-dimensional (3D) structure and the high level of tissue organization. Thus, we use bioprinting to produce highly ordered contractile muscle tissues. With increasing tissue model complexity, the cultivation as well as the read-out are becoming more demanding. In this study, we produced functional human skeletal muscle tissues in a specialized 24 well plate. Each well contained two posts around which the muscle tissue formed. With integrated electrodes, the muscle tissue was electrically stimulated and contractions were monitored optically. Human skeletal muscle-derived cells (SkMDCs) mixed in Matrigel are deposited in inkjet-mode around the posts into the wells. After differentiation of the tissues and formation of myofibers the constructs are stimulated with electrical pulses resulting in tissue contractions. Contractile forces of about 400 µN were determined using a force measurement set-up. These forces were not able to bend posts made of polypropylene as previously published [1] because the post were too stiff and unflexible. Thus, in this project, different thermoelastic polymers (TPEs) were injection molded to produce softer posts with different stiffnesses. The posts made of TPE were tested via cellular force microscopy (CFM) to determine post deflection when applying a defined force of 400 µN. The post deflection will be monitored optically and serve as a quantification of muscle contractility/activity. The goal of the project is to develop an automated platform to produce and cultivate human muscle tissues suspended between two flexible posts. In an incubation chamber, the tissues are then subjected to electrical stimulation leading to post deflection, which is monitored with a camera. With this system 24 similar human muscle tissues are produced that can be used to monitor drug effects, while analyzing contraction differences. In the end, this platform may lead to a reduction in animal experimentation because it is human cell-based, more standardized and medium throughput-compatible.

INTRODUCTION: A bone tissue adhesive must bond to protein and mineral surfaces, in wet and fatty environments [1]. A new, phosphoserine modified calcium phosphate cement (PM-CPC), which acts as a tissue adhesive, is described herein. PM-CPC strongly bonded multiple tissue types (1-4 MPa in shear, cortical bone), cured rapidly in liquids, and contained biocompatible precursors [2]. The cured adhesive retained many of the beneficial properties of the base material (ceramic), including supporting cell proliferation for bone scaffold/tissue engineering applications.

METHODS: Adhesive was prepared by mixing O-phospho-L-serine (Flamma) with alpha tricalcium phosphate (αTCP), and/or calcium silicate (CaSi), and water (0.25 L/P). Shear test Fresh bovine cortical bone tissue was cut into cubes (1 cm³), 0.2g of PM-CPC was applied to the surface, and cubes were cured in water at 37°C for 24 hours. A shear force was applied at 1mm/minute on an MTS (Shimadzu AGS-X). The adhesive microstructure was investigated with x-ray diffraction (D8 Advance, Bruker) and scanning electron microscopy (Merlin SEM, Zeiss). Cytocompatibility PM-CPC or brushite was injected by syringe, cured for 3 minute, leached in 200mg/mL DMEM for 24 hours, neutralized and sterile filtered. The same process was repeated on the raw material powders (40mg/mL). Viability was determined in human dermal fibroblasts (HDFn) by alamar blue fluorescence (Invitrogen, 10% solution, 24h exposure) at 560nm/590nm (Tekan plate reader, normalized to untreated cells).

RESULTS & DISCUSSION: Various PM-CPC formulations produced strong bone adhesion, up to 380N (average, ≈2-3MPa). PM-CPCs were extremely tacky and bonded hard and soft tissues, and biomaterials such as collagen, underwater, without needing surface treatments (polish, etch). The set adhesive was disordered (XRD amorphous), and the internal architecture contained a unique organic/inorganic interface. Extracts from brushite produced greater cytotoxicity than PM-CPC formulations. The pH of the adhesive depended upon the ratio of acidic amino acid to basic calcium salt. Though formulations with low pH were cytotoxic, neutral formulations and extracts were cytocompatible (>80% viability).

CONCLUSIONS: PM-CPC was cytocompatible and bonded tissues stronger than other ceramics or naturally derived adhesives. Simple phosphorylated amino acids produce entirely novel properties in calcium phosphate and silicate bioceramics.

INTRODUCTION: Cell signalling pathways such as the Wnt pathway and Trek ion channel signalling are important regulators controlling cell fate and play roles in orchestrating neuronal development. These pathways are therefore attractive targets for development of modulators that regulate signalling activity and neuronal precursor cell behaviour. Cell receptors that initiate signalling cascades and neural progenitor differentiation can be targeted using ligand functionalised magnetic nanoparticles (MNP). Alternating magnetic fields can then be used to induce MNP torque or twisting. The translational force applied to the target receptor through MNP may induce receptor activation or opening of ion channels thereby triggering differentiation pathways. The aim of this research was to investigate the effects of remote activation of the Wnt receptor Frizzled and Trek1 K⁺ channel using MNP and magnetic fields and to assess neuronal differentiation of progenitor cells in response. The translational aspects of this approach was also investigated using rat brain slices, cultured ex vivo, which were injected with MNP labelled neuronal pre-cursor cells and magnetically stimulated.

METHODS: Target receptor expression was assessed in SH-SY5Y and neural progenitor cells using rtPCR. 250nm MNP were coated with peptides or antibodies allowing MNP tagging to Frizzled/Trek receptors. Remote MNP-receptor complex stimulation was performed in 1h-3h sessions using alternating magnetic field gradients provided by a commercial magnetic force bioreactor. Downstream signalling activity was monitored by tracking β-catenin mobilisation and TCF/LEF luciferase reporter activity. Neuronal marker expression was then probed using immunohistochemistry both in vitro and in ex vivo embryonic rat brain slices to assess the effects of remote MNP mediated signalling activation on neuronal differentiation of injected progenitor cells.

RESULTS & DISCUSSION: Expression of Wnt receptors Frizzled1, 2 and the Trek1 K⁺ channel were confirmed in SH-SY5Y cells with increases in Frizzled expression observed during neuronal differentiation. β-catenin mobilisation and TCF/LEF luciferase reporter activity both increased in response to MNP and magnetic field stimulation. Expression of dopaminergic markers DAT and TH was augmented in vitro in MNP labelled monolayer cultures stimulated with magnetic fields. In ex vivo rat brain slices marker expression was maintained in the injected MNP labelled neuronal progenitor cells.

CONCLUSIONS: Our results demonstrate that remote activation of cell signalling pathways using targeted magnetic particles and alternating magnetic fields can be used to influence neuronal signalling and precursor cell differentiation. This unique approach opens a potential avenue for novel therapeutic treatments, in the form of injectable cell therapies, with potential applications for treating neuro-degenerative diseases such as Parkinson’s disease.

INTRODUCTION: The need of new biomaterials to replenish the loss of muscle mass is currently a challenge. While the implant of extracellular matrix (ECM) from decellularized tissues provide the best biocompatible scaffold, on the other hand ECM alone produce limited muscle recovery. We are now aware that several intercellular signals mediating tissue renewal, vascularization and immune regulation, are convoyed via extracellular vesicles (EVs), biologically active microparticles composed of a lipid bilayer produced by cells. The aim of this work is to analyze the muscle regeneration in a murine model of volume muscle loss after implant of ECM engineered with EVs.

METHODS: ECM samples were obtained using a detergent-enzymatic protocol and were embedded with EVs isolated from Wharton Jelly mesenchymal stromal cells (EV-MSC) and BJ fibroblast cell line (EV-BJ). EVs were obtained through ultrafiltration, characterized by citofluorimetric analysis, and quantified with MTA and qNano instruments. ECM-EVs were transplanted in mice after tibialis anterior damage (ECM-PBS and ECM alone were used as control). 72 hours post implant, EVs local injection was performed. After 7, 15 and 30 days, samples were analysed by histology, immunofluorescence and qPCR.

RESULTS & DISCUSSION: The macrophagic response in mice EV-MSC treated was clearly directed toward tissue rebuilding as confirmed by qPCR results on M2 and myogenic markers. 30 days post implant the fibrosis (collagen quantification) was significantly reduced in the same group of mice. vW+ cells -indicating neo-angiogenesis- and new born centrally nucleated fibers (CNFS) where present in a statistically higher percentage (**==p<0.005;****=p<0.0001.) again in EV-MSC treated mice in respect to the other experimental groups.

CONCLUSIONS: These preliminary results underlined the pro regenerative action of EV-MSC in a chronic model of volume muscle loss.

INTRODUCTION: Cell Therapy has been explored as potential of Critical Limb Ischemia (CLI) in alternative to traditional interventional approaches. Despite the initial promising results, cell therapy showed limitations in cell retention and absence of supportive environment. To overcome these limitations, we propose the design and development a new cells delivery system based on a hybrid scaffold able to stimulate reparative angiogenesis embedding vascular cells (pericytes and endothelial cells) in a mouse model of peripheral ischemia.

METHODS: The development of the hybrid scaffold was divided in two main steps: 1) composite scaffold fabrication and 2) cellularization. 1) Using a customized 3D printer, synthetic structures were fabricated with the shape of channels and woodpile. Polycaprolactone (PCL) 10% and Poly-lactic-co-glycolic acid (PLGA) (15%) were used to compare the effect of different mechanical properties. The synthetic structures were then covered with a layer of gelatin (GL) electrospun nanofibers crosslinked with γ-glycidypropyltrimethoxysilane (GPTMS), forming a nanometric network with adhesive features similar to those of the natural ECM. Morphology and mechanical properties of the scaffolds were characterized through SEM and tensile testing. 2) Adventitial Progenitor Cells (APCs), isolated from saphenous vein, were seeded at 10,000 cells/cm² onto PCL- and PLGA-based scaffold for 5 days to create a confluent layer. Cell density, proliferation and viability were performed. On top of the confluent layer of APCs, a patterned co-culture of APCs and HUVECs were then bioprinted. A hydrogel solution formed by 6% Sodium Alginate and 13% F127 Pluronic was loaded with a co-culture of APCs and HUVECs in ratio 1:4 and density of 4million/ml, extruded in lines with a Bioprinter and crosslinked with 20mM CaCl₂ to guarantee spatial organization. To validate the approach, scaffold which performed better in vitro were implanted with and without cells around the femoral artery of mice with unilateral LI. The end-points of the test were evaluated with microCT.

RESULTS & DISCUSSION: Scaffolds with channel and woodpile shapes were successfully fabricated, achieving line width of 121±5μm and thickness of 75±5μm, Mechanical properties showed significant differences depending on the geometry and on material, with the PCL displaying values closer to the tissue of femoral artery. In vitro assays showed higher performances of the channel-shaped scaffold compared to woodpile ones, while no differences were noticed between PCL and PLGA. Viability of Bioprinted APCs and HUVECs was observed always around 70%, and the aligned pattern maintained in the period of the investigation. Based on these results, PCL- and PLGA-channel shaped scaffold with and without cells were implanted around the occluded femoral artery. Flowmetry assessment showed that the group implanted with cellularized PLGA-AG/PL recovered faster as compared with vehicle (11 vs. 18 days, respectively, p=0.01). Qualitative analysis of vasculature tree was evaluated with microCT at time point of 3 weeks.

CONCLUSIONS: Data show the potential of the novel hybrid scaffold as cell delivery system to improve the efficacy of cell homing and increasing pro-angiogenic effect in ischemic tissues.

INTRODUCTION: Traumatic injuries affecting articular cartilage do not heal spontaneously and often lead to osteoarthritis. As opposed to adult tissue, injured fetal cartilage undergoes scarless healing1. This difference might be due to inherent variance of mesenchymal progenitor cells. Even though advantageous effects of MSCs on cartilage repair have been demonstrated, use of cells as therapeutics is limited by several factors2. Hence recently, exploiting paracrine signaling of cell secretomes has gained attention as potential therapy 2. In this work we aimed to evaluate the effect of secretomes derived from fetal and adult MSCs for cartilage regeneration.

METHODS: Ovine primary cells (MSCs and Chondrocytes) were isolated from healthy donors following standard procedures for both adult and fetal donors. Experiments were designed to simulate injury to adult chondrocytes followed by treatment with secretome derived from either adult or fetal MSCs. MSCs were left to adhere overnight. Following medium change (all experiments were performed in serum free medium - STEM MACS), secretome was produced for 24 hours and subsequently used as treatment. Adult chondrocytes were exposed to inflammatory stimuli (10 ng/µl IL1β and 10 ng/µl TNFα) for 24h before treatment with either fetal or adult secretome. Chondrocyte migration (scratch assay), proliferation (PicoGreen) and metabolic activity (MTT) were evaluated in monolayer, while gene expression was evaluated in pellet culture. Q-PCR was performed for several inflammation markers, as well as extracellular matrix (ECM) degradation and production related genes.

RESULTS & DISCUSSION: Migration, proliferation and metabolic activity assays showed differences in the effects induced by fetal compared to adult MSC secretome. In both cases, MSCs derived secretome increased chondrocyte migration and proliferation compared to untreated chondrocytes. Gene expression revealed anti-inflammatory properties of adult and fetal secretomes although differences between the two cell sources were found. Also expression of genes related to ECM production was differently regulated by secretomes of fetal and adult MSCs.

CONCLUSIONS: Results of this study indicate a positive influence of secretomes derived from fetal and adult MSCs on adult injured chondrocytes. Variance in their effects might be due to key factors driving fetal regeneration as compared to adult repair. While the underlying mechanisms of action still need to be investigated, the secretome derived from fetal MSCs might represent a valid treatment option to achieve cartilage regeneration. Future studies will need to address the qualitative as well as quantitative differences in protein content between adult and fetal MSC secretomes as well as confirm our current results in vivo.

The catabolic-to-anabolic shift in the osteoarthritic cartilage after knee joint distraction in dogs occurs after the distraction period
M. Teunissen 1, J. Popov-Celeketic 2, K. Coeleveld 3, B.P. Meij 1, F.P.J.G. Lafeber 2, M.A. Tryfonidou 1, S.C. Mastbergen 2

INTRODUCTION: Knee joint distraction (KJD) is a joint-preserving treatment strategy for severe osteoarthritis (OA) that provides long-term clinical and structural improvement [1]. Data from both human trials and animal models indicate clear cartilage regeneration from 6 months and onwards post-KJD [1, 2]. However, recent work showed that during distraction, the balance between catabolic and anabolic indicators is directed towards catabolism, as indicated by collagen type 2 markers [3], proteoglycan (PG) turnover and a catabolic transcription profile [unpublished data]. As such, this study investigates the cartilage directly and 10 weeks after joint distraction in an animal model in order to elucidate the shift from a catabolic to an anabolic cartilage state.

METHODS: Knee OA was induced bilaterally in 8 dogs according to the groove model [2]. After 10 weeks of OA induction, the right knee received joint distraction, employing the left knee as an OA control. After 8 weeks of distraction, and after 10 weeks post-KJD, 4 dogs were euthanized. Respectively, macroscopic cartilage degeneration, PG content (Alcian Blue), and PG synthesis (35SO42-incorporation rate) were assessed [2].

RESULTS & DISCUSSION: Directly after KJD, macroscopic cartilage damage of the right tibial plateau was higher compared to the left OA control (OARSI score: 1.7±0.2 vs 0.6±0.3; p < 0.001). 10 weeks post-KJD this difference persisted (OARSI score: 1.4±0.6 vs 0.6±0.1; p < 0.05). Biochemical analysis of the tibia cartilage directly after KJD revealed a lower PG content (20.1±10.3 mg/g vs 23.7±11.7 mg/g). At 10 weeks post-KJD this difference in PG content was less (24.8±6.8 mg/g vs 25.4±7.8 mg/g). The PG synthesis rate directly after KJD appeared significantly lower vs. OA (1.4±0.6 nmol/h.g vs 5.9±4.4 nmol/h.g; p < 0.001)). However, 10 weeks post-KJD this difference was not detected (3.7±1.2 nmol/h.g vs 2.9±0.8 nmol/h.g), and the synthesis rate in the distracted knee was increased compared to directly after distraction (p < 0.01).

CONCLUSIONS: Further in-depth investigation of the material is ongoing; these first results suggest that the shift from a catabolic to an anabolic state occurs within the first weeks after joint distraction, mostly reflected in the biochemical changes. As such, the post-distraction period seems to be essential in identifying key-players that support intrinsic cartilage repair.

INTRODUCTION: Reactions leaded by diffusion forces confined at the interface between two immiscible liquids present singular characteristics difficult to replicate in other environments. Although these systems have proven to be of great interest for preparing self-assembled physical peptide-based hydrogels [1], very little efforts have been exerted employing covalently cross-linked polypeptides, such as elastin-like recombinamers (ELRs) [2]. While other biomaterials are limited in terms of tunability, ELRs offer the possibility to introduce both specific bioactivities and physico-chemical reactivities. Herein has been exploited these two particularities, the employment of free-catalyst click modified ELRs versions in combination with a two-phase solution to produce thin moldable elastin-based membranes.

METHODS: Two ELRs were designed, encoded in double strand DNA plasmid and expressed in E. Coli bacteria. Purified polypeptides were chemically modified to incorporate the click chemistry groups, dissolved at the same concentration in an aqueous and an organic immiscible solutions previous mixing. Four different concentrations were assayed to prepare the membranes inside a tubular container. Isolated membranes both hydrated and lyophilized were observed by ESEM and SEM microscopy. Franz cells were used to study the diffusion rate of five FITC-dextran molecules in a 4-150kDa range during 21 days.

RESULTS & DISCUSSION: A tailored device was designed to contain the two-phase system. The initial concentration of the two solutions put in contact determined the thickness of the membranes obtaining the thinnest thickness with the lowest concentration. Similarly, the smallest fluorescent labelled polysaccharide depicted the fastest diffusion rate finding half-diffusion times starting from 3 up to 9 days. Both hydrated and lyophilized versions of the membranes showed an internal and superficial porous appearance.

CONCLUSIONS: A reproducible methodology has been implemented to construct tunable soft membranes in terms of both thickness and diffusive properties. In addition, the high biocompatibility of the recombinant elastin-based materials employed enables their use as a versatile scaffold for developing new systems for tissue-engineering applications

INTRODUCTION: Tissue engineering is developed to construct a functional tissue to repair or restore the damaged tissues/organs [1]. For instance, vascularization plays an important role, which enables to remove wastes and deliver nutrients. In addition, various tissues like skeletal muscle have uniaxially aligned vasculature to sustain the viability of the anisotropic tissues. Since microcirculation is derived from the longitudinally oriented blood vessels [2], an aligned microstructure should be achieved for vascularized skeletal muscle. Thus, an aligned micro/nanofibrous scaffold fabricated via cell electrospinning will be proposed to provide physical cues to induce cell alignment and elongation.

METHODS: Human umbilical vascular endothelial cells (HUVECs) at 5×10⁶ cells/mL were mixed with alginate/polyethylene oxide (PEO) solution as a bioink. Then, the bioink was electrospun onto the polycaprolactone (PCL) with and without aligned topological cues. Then, C2C12 myoblasts at 1×10⁵ cells/mL myoblasts were seeded on the specimens.

RESULTS & DISCUSSION: To assess feasibility of cell electrospinning using HUVECs, initial cell viability was measured by live/dead staining. Electric field was varied from 0.050 to 0.125 kV/mm, and over 90% cell viability was observed for 0.050-kV/mm and 0.075-kV/mm electric field. However, cell viability significantly decreased for 0.100-kV/mm electric field. Moreover, cell morphology was captured by CD31 at 14 days. The HUVECs on aligned PCL stretched along the micro/nanopattern while the HUVECs on non-aligned PCL were in ellipsoidal shape. This aligned vascular structure accelerated myogenesis and cell-cell interaction among myoblasts and HUVECs.

CONCLUSIONS: In brief, aligned micro-/nano-pattern guides cells in anisotropic structure.

INTRODUCTION: Mesenchymal stem/stromal cells (MSC) are able to regulate tissue repair after injury, including the prevention of excessive fibrosis. Extracellular vesicles (EV-MSC) were shown to mediate most of MSC effects and could be involved in their antifibrotic activity. However, the mechanisms of these effects, particularly the role of microRNA (miR) within EV-MSC, are poorly understood.

METHODS: Human adipose-derived MSC (primary and immortalized line ASC52telo, ATCC) were used to analyze the content of EV-MSC. Ultrafiltration was used to isolate EV from MSC conditioned medium. Exosomal RNA was isolated and libraries for mass parallel sequencing for the analysis of miR were constructed. Using the TargetScan7.2, HMDD, miR2Disease, miRwayDB databases, miR associated with the development of fibrosis and their representation in EV-MSC were analyzed. Clustering was performed using the David database. To assess the contribution of selected miR (miR-21 and miR-29) to the biological activity of EV-MSC, vesicles transfected with anti-miR-21 or anti-miR-29 were added to fibroblasts treated with TGF-β to induce myofibroblast phenotype.

RESULTS & DISCUSSION: From 2652 miR 270 were detected in the EV-MSC. According to the results of cluster analysis it was shown that among the targets of detected miR there were factors associated with the development of fibrosis. 372 unique miR and 20 genes are associated with TGF-β, of which 24 miR are reliably represented in EV-MSC; 368 unique miR and 22 genes are associated with actin, 23 are represented; 21 miR and 1 gene are associated with fibrosis, 21 are represented; 5 miR and 1 gene are associated with collagen, 5 are represented.

Thus, multiple miR might be involved in EV-MSC-mediated regulation of fibrosis. Impact of selected miR were validated by the model of TGF-β-induced fibroblast differentiation into myofibroblasts. The addition of EV-MSC inhibited TGF-β-induced differentiation fibroblasts in myofibroblasts. Addition of EV transfected by scramble or miR-21 inhibitor did not affect EV-MSC-mediated inhibition of differentiation. Transfection of vesicles with miR-29 inhibitor reduced the effect of EV-MSC on TGF-β-induced differentiation of fibroblasts into myofibroblasts.

CONCLUSIONS: Our data indicates the impact of miR in antifibrotic activity of EV-MSC. Further study will enable the development of drugs and biomaterials based on miR within EV-MSC that could be promising for regenerative medicine and antifibrotic therapy.

INTRODUCTION: Vocal fold scars are a common multietiological disease appearing with persistent voice impairment. Due to a highly complex microstructure of the extracellular matrix’s (ECM) proteins in the vocal fold mucosa, it is one of the most difficult problems in laryngology, in spite of the great variety of existing treatment techniques. In our study, we follow the regenerative effects of mesenchymal stem cells (MSC) on the structure of vocal folds with cicatricial lesions.

METHODS: Twelve laboratory rabbits underwent a surgical modeling of mature scars of the vocal folds. Ninety days after the first surgery, the vocal fold scar was excised with the simultaneous implantation of autologous bone marrow derived MSC (6·10^5 cells) or a saline for the experimental or control groups, respectively. The restoration of the vocal folds ECM was studied 90 days post-implantation via a histological estimation of 11 pathological signs, scar thickness measurement, immunohistochemistry for collagen type I and type III and atomic force microscopy (AFM) studies.

RESULTS & DISCUSSION: The analysis of the semi-quantitative data detected significant differences in the following morphological signs: lack of fibroblasts, irregular architectonics of collagen fibers, density of collagen fibers with the prevalence of alteration in the control group (p-value 0.086). There was also a visible trend of a scar width reduction from the control to the MSC-treated group. According to the data of immunohistochemical analysis, the collagen type III content was by 45.5% lower than that of collagen type I in the control group (p<0.0001). At the same time, no distinguishable difference in the intensity and prevalence of staining for collagens type I and type III was observed in the intact vocal folds and in the MSC-treated group. The AFM study revealed a statistically significant increase in the average Young’s moduli (p-value 0.013) in the control group and returning to their initial values (p-value 0.59) in the MSC-treated group. The thicknesses of collagen fibrils in the intact vocal fold ECM was slightly higher compared to the scar tissue in the control group. In MSC-treated group this indicator did not differ from the intact tissue.

CONCLUSIONS: Our results have shown that the ECM structure in the scar tissue of the vocal folds with implanted MSC is more similar to that in the normal mucosa of the vocal folds than to that of the untreated scars. According to our study results, AFM provides clear and understandable data for accurate assessment of the recovery of the vocal folds ECM proteins and may be used in further studies.

INTRODUCTION: Regenerative therapies that restore the function of damaged tissues and organs via the use of a patient’s own cells is a highly desirable cure for many presently incurable pathologies and diseases. Over the last years, biological advances have allowed for the expansion and implementation of primary human and stem cells for the production of nearly any human tissue and organ like cellular masses (organoids) ex vivo, leading the way for their use in regenerative therapies. Nevertheless, state of the art technologies do not allow for the undamaged release of produced tissue or cell assemblies from their culture platform, which is a necessary step before their clinical application. Here, we highlight the recent progress of our lab in the development of orthogonal synthetic strategies for the formation and functionalization of biodegradable biohybrid hydrogels composed of covalently cross-linked four-arm poly(ethylene glycol) and various glycosaminoglycan (GAG) polysaccharides with peptide conjugates. The combination of these biohybrid materials with an orthogonal, enzymatically degradable peptide material concept was utilized to create a new bio-orthogonal approach for ex vivo tissue production (Figure 1) thus utilizing the material as a bioreactor platform. The potential of this technique was shown by formation of a human cornea endothelial lamella tissue suitable for surgical implantation in descemet membrane endothelial keratoplasty (DMEK).

METHODS: Human corneal endothelial cells (HCEC) were seeded on functionalized hydrogel culture carriers and cultured until a functional tissue was formed. The culture carrier was subsequently enzymatically degraded with FXa enzyme, which is both specific and gentle, to release free-floating cell sheets. The formed tissue was characterized in terms of viability (live-dead) and functionality (marker proteins).

RESULTS & DISCUSSION: Release of the cultured HCEC layers show the suitability of enzymatically-degradable hydrogels for HCEC sheet generation of physiologically relevant size (~1 cm) as shown in the Figure 1. The cells cultured on the hydrogels exhibit a regular morphology and appropriate metabolic activity. Cells were positive for expression of function-associated marker proteins ZO-1, Na+/K+-ATPase, and the extracellular matrix proteins fibronectin, laminin and collagen type IV. The detached, floating HCEC sheets were transplanted onto porcine corneas in vitro to show their suitability as a potential medical transplant.

CONCLUSIONS: This technology allows any live cells, tissue, or organoids, to be encapsulated, manipulated, and released from this hydrogel materials without damaging the biological sample. Father application will include human umbilical vein cells (HUVC) for vascular regeneration and human fibroblast for connective tissue regeneration.

ACKNOWLEDGEMENTS: Financial support was received from EXIST 03EFJSN114.
Triple function in one coating: Towards anti-adhesive, bactericidal, and cell instructive medical implants

INTRODUCTION: Strategies to inhibit bacterial colonization are crucial to prevent infection on biomaterial surfaces, a major threat in modern medicine [1]. However, simultaneously achieving efficient antibacterial potential while positively supporting host eukaryotic cells functions remains a challenge for successful biomaterial-host tissue integration [1]. Here, we describe a method for the development of a trifunctional coating that repels contaminating bacteria, kills those that adhere, and promotes osteoblast adhesion.

METHODS: Titanium model substrates were functionalized with polyethylene glycol (PEG) via electrodeposition. Subsequently, the polymeric layer was further coated with a peptidic platform (PTF) combining cell adhesive (RGD) and antibacterial sequences (LF1-11 peptide) [2] using silanization. Physicochemical characterization was performed with contact angle analysis, interferometry, XPS and FTIR. The response of sarcoma osteogenic cells (SaOS-2) was evaluated in vitro by means of cytotoxicity test (LDH) and immunofluorescence analysis. The antibacterial activity was measured using Streptococcus sanguinis via live/dead and SEM analysis.

RESULTS & DISCUSSION: PEG coatings significantly inhibited protein adsorption and SaOS-2 attachment; however, the presence of cell adhesive domains (PTF) efficiently rescued osteoblast adhesion, yielding higher values of cell attachment and spreading compared to controls (p<0.05). The repellent properties of PEG resulted in a significant inhibition of S. sanguinis attachment (p<0.05). This antibacterial potential was further increased by the bactericidal peptide, yielding values of bacterial adhesion below 0.2% (p<0.05) [3].

CONCLUSIONS: The antibacterial properties of our coating strategy respond to the antifouling character of PEG, which repels bacteria, and the bactericidal properties of the PTF. Such combined effect drastically inhibited the adhesion of S. sanguinis. Simultaneously, the coating supported very good levels of osteoblast adhesion. Taken together, this new trifunctional coating represents a promising approach to address both bacterial infection and poor material osteointegration.

ACKNOWLEDGEMENTS: Financial support from the MINECO/FEDER (RYC-2015-18566, MAT2015-67183-R and MAT2017-83905-R) and the AGAUR (2017 SGR1165) is appreciated.

¹G.E.R.N. Tissue Replacement, Regeneration & Neogenesis, Dept. of Orthopedics and Trauma Surgery; Albert-Ludwigs-University of Freiburg, Hugstetter Straße 55, 79106 Freiburg, Germany ²Department of Biomedical Engineering, University of Michigan, Michigan, MI 48109, USA

INTRODUCTION: Automated, user-independent quantitative analysis of biological images for analyzing cell morphology is of great need as high amounts of morphological data could be generated and correlated with biological readouts such as mRNA expression. However, single cell shape analyses are difficult in complex biological situations such as high cell densities. Here, we present a novel trainable machine learning tool for automated and exact single cell measurement in complex biological situations.

METHODS: A cell segmentation tool, based on the WEKA machine learning algorithm was developed for single cell measurement in complex biological situations. Throughout the process, step by step evaluation situations were established and used in a feedback loop for software-improvements. Then, human users vs. scripted WEKA was compared in standardized tests.

RESULTS & DISCUSSION: First, the WEKA script was adapted to establish so-called image classifiers and image regions of interest (ROIs) representing e. g. the nucleus were used to train the “nucleus classifier” and others. These classifiers were applied for segmenting images into nucleus, cytosol, protrusions and background, which enabled the automated, trainable segmentation of cells vs. background. Separation of neighboring cells was achieved using a watershed algorithm. Combining these approaches allowed reliable single cell separation; an segmentation illustration of two adherent hMSCs derived from mixing and seeding hMSCs stained with the CellTracker Blue with hMSCs stained with CellTracker Green. First tests demonstrated that the scripted WEKA was significantly faster than two human users (p<0.05). Assessing accuracy, we used the difference in pixels between the segmented images generated by the trained algorithm vs. human segmentation. The data demonstrated significant differences in the amount of pixels between the two human users and between the algorithm and the human users, indicating significant quantitative differences in the final segmentation result. Interestingly, there were no significant pixel differences between repeated algorithm segmentations, indicating a high reproducibility. After adapting the algorithm to quantify a panel of quantitative shape descriptors such as cell area, aspect ratio (AR), roundness, length, width, circularity, and solidity, these data was further used to compare human users vs. scripted WEKA. Statistical tests demonstrated significant differences in shape descriptors between the WEKA and untrained human users (p<0.05) but not trained users.

CONCLUSIONS: We established an automated, user-independent, user-friendly, and exact machine learning tool for quantifying the geometrical shape of single cells. Moreover, these tests demonstrated that a trained subjective user can be as good as the trained WEKA script but that an untrained user was not as good as the trained WEKA script.
Towards understanding why nanoclays are osteogenic

INTRODUCTION: Laponite clay nanoparticles are emerging as a new class of biomaterials with exciting opportunities for regenerative medicine applications [1]. High profile studies have demonstrated [2] the osteogenic properties of Laponite, however, the mechanism(s) underlying nanoclay bioactivity remain poorly understood. Cell uptake and release of degradation products such as Li⁺ are frequently cited mechanisms. In this work, we investigated the effect of Laponite clay nanoparticles on osteogenic differentiation of Human Bone Marrow Stromal Cells (HBMSCs) and the role of these frequently proposed mechanisms for clay bioactivity.

METHODS: i) role of Laponite degradation products: Various Li⁺ modified Laponite formulations were generated and their effect on HBMSCs osteogenic differentiation was investigated at both basal and osteogenic medium conditions at clay doses of 0 – 100 µg/mL. ii) Role of direct Laponite/ALP interaction: the adsorption kinetics of ALP enzyme on clay surfaces was investigated at physiological conditions (pH = 7.6 & 37°C) and the catalytic activity of adsorbed vs. free enzyme was measured. iii) Role of Laponite endocytosis: HBMSCs were pre-treated with chlorpromazine hydrochloride (CPZ), a clathrin-mediated endocytosis inhibitor, for 2 hours, then incubated with both CPZ (5 µg/mL) and Laponite (0 – 100 µg/mL) in basal and osteogenic conditions for 72 hours. At day 3, ALP activity of HBMSCs was measured using the p-nitrophenol phosphate (pNPP) colorimetric assay.

RESULTS & DISCUSSION: Laponite nanoparticles induced osteogenic differentiation of HBMSCs at an early stage in a dose-dependent manner. This was confirmed by a significant increase in ALP Activity and upregulation of osteogenic genes (e.g. RUNX2 & Collagen I) at day 3, as well as enhanced Ca-P mineral deposition at day 14. Modified Laponite chemistries achieved variation in their Li⁺ content. However no attenuation or increase in clay bioactivity was observed between the modified clays tested. ALP enzyme displayed a strong binding affinity for Laponite, following a Langmuir adsorption isotherm. However Laponite significantly reduced ALP activity rather than enhanced it (V_max of adsorbed enzyme < free enzyme). Finally, the addition of an endocytosis inhibitor did not show significant effect on the dose dependent (0 – 100 µg/mL) osteogenic effect of Laponite on the cells.

CONCLUSIONS: Cellular uptake of clay nanoparticles and their subsequent degradation, has been frequently cited as the main mode of action for clay bioactivity. Our data, however, indicate that clay exert their osteogenic properties extracellularly and independent of their degradation products. Furthermore, our data confirms that such early-observed clay-mediated increase in ALP activity was not due to a direct clay/enzyme interaction, suggesting a role for biophysical models, such as, clay-cell membrane and clay-ion interactions in cell culture medium [2]. Studies seeking to elucidate these mechanism(s) are ongoing.

INTRODUCTION: The performance of amniotic epithelial stem cells (AECs) has retained great attention in the field of regenerative medicine given the fact of their ability to differentiate into tenogenic lineage. To increase their potential to completely regenerate tendon injuries, it is essential to develop innovative tissue engineering solutions as tendon bio-mimetic scaffolds possessing mechanical and structural properties similar to the native tissue. In this context, PLGA electrospun scaffolds with highly aligned fibers and different diameter size were fabricated to test and compare their mechanical properties and tenoinductive potential on AECs.

METHODS: PLGA electrospun scaffolds with highly fiber alignment possessing two different fiber diameter size (PLGA1 with 1.25 µm and PLGA2 with 2.5 µm), and PLGA with randomly oriented fibers, used as control, were fabricated. The produced scaffolds were characterized for their structure (SEM), their wettability, their mechanical properties, and their influence on AECs. In particular, seeded ovine AECs onto the PLGA electrospun scaffolds were compared for DNA quantification (4h and 48h), viability (Calcein AM and propidium iodide), spatial distribution and morphology (Phalloidin), and teno-differentiative potential by analyzing collagen type 1 (COL1) protein and gene expression of mature tendon markers (COL1 and TNMD) after 24h, 48h, and 7 days culture.

RESULTS & DISCUSSION: PLGA1 with small fiber diameter size showed a high-water uptake percentage value compared to PLGA2 (p<0.05) while both values were significantly lower than that of PLGA-R (p<0.05). Additionally, both aligned scaffolds possessed similar ultimate tensile stress value (p>0.05) whereas fracture strain value was significantly higher in case of PLGA2 compared to PLGA1 (p<0.05). In fact, it was significantly higher on PLGA-R respect to PLGA1 and PLGA2 scaffolds (p>0.05), whereas in PLGA2 scaffold it was slightly higher compared to PLGA1 (p<0.05). Interestingly, spindle-like tenocyte morphology of AECs seeded onto both PLGA aligned fibers was observed just after 24h of culture, whereas cells on PLGA-R retained their cobblestone typical morphology (p<0.05). The number of elongated cells increased significantly by increasing the culture time on both aligned fiber scaffolds with a faster elongation rate onto PLGA1 (p<0.05), confirming low cell proliferation. Moreover, AECs seeded onto both aligned fibers expressed COL1, the main protein of a tendon, in their cytoplasm already at 24h of culture. These results were also confirmed by analyzing mature tendon specific markers COL1 and TNMD gene expressions which have shown an increasing upregulation in both PLGA scaffolds with aligned fibers (p>0.05) during the analyzed culture periods, compared to those in PLGA-R scaffolds (p<0.05).

CONCLUSIONS: Fiber diameter size of electrospun scaffold and not just its topology can be challenging by regulation cell fate and teno-differentiative potential.

Human placenta derived membrane is a favourable natural biomaterial for vascular tissue engineering
M.H. Farjoo¹, H. Niknejad¹
Presenting Author: Mohammad Hadi Farjoo, m.farjoo@sbmu.ac.ir

INTRODUCTION: Human placenta derived amniotic membrane, as a natural biomaterial, has many characteristics, such as low immunogenicity, antibacterial, anti-inflammation, anti-fibrosis, and rich extracellular matrix ingredients, which make it a promising source for vascular tissue engineering. In addition, a single layer of amniotic epithelial stem cells (similar to a monolayer of endothelial cells in the vessels) which have capability to differentiate into the cells of three germ layers boosts the idea of using amniotic membrane as vascular substitute.

METHODS: This work evaluated the feasibility of constructing a vascular conduit from the human amniotic membrane and implanting it in the external jugular vein of juvenile sheep. Also, endothelial differentiation capability of amniotic epithelial stem cells and angiogenesis inducing activity of epithelial and mesenchymal sides of amnion were assessed.

RESULTS & DISCUSSION: At 6 and 48 weeks after implantation, the grafts were fully patent and the internal surface was smooth, and shiny, without any sign of thrombus formation. No inflammation or fibrosis was evident. Scanning electron microscopy revealed a confluent layer of cells with normal endothelial cell morphology. There was a monolayer of cells positive for von Willebrand factor in histology sections. The combination of BMP-4 and VEGF synergistically increased the expression of endothelial markers in in vitro cultured amniotic epithelial cells. Both epithelial and mesenchymal sides of amnion showed increased angiogenesis after removing epithelial cells. Platelet aggregation and P-selectin production assays, Prothrombin time (PT), activated partial thromboplastin time (aPTT), clotting time (CT) and haemolysis (%) tests showed that both the epithelial and mesenchymal sides of the amnion are hemocompatible.

CONCLUSIONS: The results of the current study demonstrate that the human amniotic membrane is a proper substitute for vascular tissue engineering. However, further studies will be required to investigate human amniotic membrane as an implant in the arterial circulation.
Evaluating the design and fabrication of tissue engineering scaffolds based on triply periodic minimal surfaces

INTRODUCTION: One of the routes tissue engineering research can take is to provide a scaffold, which acts as a temporary artificial extracellular matrix for cells. An important aspect of scaffold design is the variety of pore diameters required to optimize cell culture development. This work details how triply periodic minimal surfaces (TPMS) [1-2] consist of pore profiles with a variable pore diameter that could accommodate the requirements for an optimized 3D cell culture.

METHODS: Scaffold geometries were designed in Rhinoceros 3D, and their pore profiles were evaluated using a protocol developed in the visual programming language Grasshopper. CAD models were converted to printable 3D meshes and fabricated using the ProJet 3500 printer in a biocompatible polymer. Micro CT reconstructed models of 3D printed scaffolds were used to compare the fabrication accuracy of these pore profiles. Scaffolds were also seeded with human endothelial cells (HECV) in order to observe their attachment and viability using confocal microscopy.

RESULTS & DISCUSSION: The design work helped to develop a protocol for the 3D modelling and fabrication of bio-mimetic scaffolds geometries. The comparative analysis of Micro CT reconstructed models to CAD models showed how variable pore profiles can be fabricated using 3D printing. This profile results in a gradually changing pore diameter, which can range from 100 µm to 1000µm depending on single unit size, and the specified wall thickness required for stable fabrication. The cell seeding work provided insight into how endothelial cells arrange themselves within a pore.

CONCLUSIONS: The results of this work show that TPMS geometries may be a suitable candidate for scaffolds with bio-mimetic architecture and provide variable pore profiles that could play a role in optimizing 3D cell culture.

ACKNOWLEDGEMENTS: This PhD was funded by University of Wales scholarship. Micro CT was performed by Professor Richard Johnston from the Materials Research Centre in Swansea University. Cell Seeding work was done with Professor Keith Morris at CSHS in Cardiff Metropolitan University.

INTRODUCTION: Fellowships are common in many countries, whereas other countries do not offer special training after residency. Therefore many doctors seek for a fellowship after completing their residency. Fellowships became an essential part of professional medical training. Finding a suitable fellowship is essential. Physicians and institutions may have different expectations regarding fellowships, which can lead to frustration and wasted resources for both. One obstacle for doctors is finding reliable feedback from previous fellows regarding a specific fellowship and being able to contact that person for further advice. In addition, for both doctors and institutions alike, financing a fellowship can also prove a challenge.

METHODS: A website was created as well as a 1 minute survey using REDCap electronic data capture tools. The project was initiated during an international Orthopaedic and Trauma meeting in Switzerland. Moreover, the website was posted on Linkedin, Facebook and a newsletter explaining the project was sent to 1749 doctors worldwide per e-mail.

RESULTS & DISCUSSION: 2 weeks after the project initiation there were 1632 visits (1091 new users) to the website from 50 countries, mainly USA (37.9%), Switzerland (36.8%), Egypt (7.2%) and Germany (3.2%). 100 surveys from participants from 24 countries were completed: Switzerland (56%), Egypt (7%), France (5%) as well as Australia, Brazil, India and the United Kingdom (3%). The main specialities were Orthopaedic & Traumatology (59%), General Surgery (12%) and Internal Medicine (6%). Most of the participants were potential fellows (43%), previous fellows (26%) or individuals and/or institutions who would like to offer a fellowship (12%). The participants were mainly interested in a fellowship database (75%), connecting to other fellows (67%), giving/receiving feedback about a fellowship (61%) or receiving financial support (41%).

CONCLUSIONS: The results of the first surveys suggest that there is an interest in an online fellowship advisor including a database for fellowships worldwide, a platform for fellows to connect to each other with the ability to give and receive feedback about a fellowship. Accordingly an IT company was assigned to build the platform with the needs of doctors and institutes in mind. Financing a fellowship remains a challenge for many participants.
Assembly of functionalized silk together with cells to obtain proliferative 3D cultures in a network of microfibers

INTRODUCTION: Tissues are built of cells integrated in an extracellular matrix (ECM) which provides a 3D network with specific sites for cell anchorage. By genetic engineering, motifs from the ECM can be fused to recombinant silk proteins. Such a silk protein, FN-silk, which harbors a motif from fibronectin, has the ability to self-assemble into microfibers under physiological-like conditions. Herein we describe a method by which mammalian cells are added to the silk solution before assembly, and thereby get uniformly integrated between the formed microfibers.

METHODS: 12 different cell types were investigated for incorporation during the silk assembly process. The studied cell types, mainly isolated human primary cells, were selected to include a wide range of adherent cells, originating from various tissues of the body. Silk was assembled to microfibers in a random foam network or aligned fiber bundles (Fig. 1). Cell spreading, viability and proliferation was investigated. The differentiation capacity of stem cells after integration into silk was also evaluated.

RESULTS & DISCUSSION: Cells with elongated morphology and distinct focal adhesion points were found already after 3h in the silk network. In contrast to parallel cultures in RGD-coupled alginate, the cells in FN-silk were highly proliferative, quickly spreading out with proliferative cells also in the innermost parts. Cells remain viable in silk for at least 90 days. The method is also scalable to macro-sized 3D cultures. Silk fibers with integrated cells are both strong and extendable, with mechanical properties similar to that of artery walls. The described method enables both differentiation of stem- or precursor cells in 3D and facile co-culture of several different cell types. For example, inclusion of endothelial cells leads to the formation of vessel-like structures throughout the tissue constructs.

CONCLUSIONS: Silk-assembly in presence of cells constitutes a viable option for 3D culture of cells integrated in a microfiber ECM-like network, with potential as base for engineering of functional tissue.

\textbf{Figure 1:} Differential Interference Contrast micrographs of the silk microfibers (white) in fiber (left) and foam (right) with mouse mesenchymal stem cells. Actin filaments are visualized by phalloidin (green) and cell nuclei by Dapi staining (blue). Scale bar = 50 µm.
Thorough investigation on the encapsulation of drugs with different wettability in thermosensitive micellar hydrogels

INTRODUCTION: Injectable hydrogels for the targeted release of therapeutics are a promising tool in the treatment of a wide variety of pathologies. In order to optimize gel design, a thorough understanding of gel/therapeutic interactions is required to predict payload release timing and its effects on gel properties. Herein, we designed thermosensitive micellar gels based on an amphiphilic poly(ether urethane) (PU), that were loaded with ibuprofen (IBU, hydrophobic drug) or ibuprofen sodium salt (IBUSS, hydrophilic salified form of IBU). IBU and IBUSS arrangement within the gels and their interactions with PU micelles were studied by rheology, dynamic light scattering (DLS) and colorimetric assay using 1,6-diphenyl-1,3,5-hexatriene (DPH) as marker of micellization.

METHODS: PU was synthesized starting from the triblock copolymer Poloxamer 407, an aliphatic diisocyanate and 1,4-cyclohexane dimethanol. Hydrogels were prepared in saline solution at a 15% w/v according to [1]. IBU and IBUSS were then loaded (1 mg/ml) and the resulting systems were rheologically characterized by strain sweep, frequency sweep and temperature ramp tests. Swelling and stability to dissolution were also evaluated. Drug/PU micelle interactions were studied by DLS and DPH assay on PU solutions (0.5% w/v) loaded with IBU and IBUSS [1].

RESULTS & DISCUSSION: Gel loading with IBU resulted in a decreased onset of the gelation process compared to PU_IBUSS and PU gels (9 °C for PU_IBU vs 14 °C for PU_IBUSS and PU). This result suggested that IBU hydrophobic nature induces its encapsulation within PU micelles during their nucleation, thus leading to the achievement of the critical micellar volume required for gelation onset [1] at lower temperature compared to the other samples. In fact, PU_IBUSS did not change its gelation onset compared to PU gel, suggesting that this drug is mainly located in the interstitial space among the micelles. DLS further proved this hypothesis, showing that micelles in PU_IBU had a significantly higher hydrodynamic diameter compared to PU_IBUSS and PU solutions (58 nm for PU_IBU vs 37 and 40 nm for PU_IBUSS and PU). Additionally, PDH assay showed that the critical micellization temperature of PU_IBU was clearly lower compared to PU and PU_IBUSS solutions (9 °C for PU_IBU vs 22 °C for PU and PU_IBUSS). Interestingly, irrespective of the nature of the encapsulated drug, drug-loading seemed to slightly accelerate the kinetics of gel formation and development compared to drug-free PU hydrogels (gelation points in frequency sweep test at 25°C were 58, 50 and 45 rad/s for PU, PU_IBU and PU_IBUSS), thus suggesting that encapsulating either hydrophilic or hydrophobic drugs do not have detrimental effects on the temperature-driven sol-to-gel transition of micellar gels. Additionally, no significant effects were observed in gel swelling and stability to dissolution in aqueous media upon drug encapsulation.

CONCLUSIONS: We reported for the first time the potential of rheology, DLS and DPH assay in characterizing drug arrangement within gels and their interaction with micelles.

INTRODUCTION: It was demonstrated that stem cells cultured in 3D environments mimicking the native niche are able to maintain their stemness [1]. The cell fate seems to be correlated to the nuclear roundish morphology, far from the spread one of adherent cells. We hypothesize that the nuclear shape results from the system of forces transmitted to the nucleus through integrins, actins, nesprins and SUN proteins. We investigate the force distribution among different structures supposed to be connected to Sun1 protein, such as lamina and the nuclear pore complex (NPC). Here we focus on the prediction of SUN1 N-terminal domain folding to understand its affinity with aforementioned structures, and therefore better characterize force transmission to the NPCs.

METHODS: According to literature, we define the SUN1 N-terminal domain ranging from 1 to 300 amino acids. I-Tasser software returns possible templates. The best template is used to obtain SUN1 N-terminal predictive model by Swiss Model Software (two further templates are under evaluation). To estimate the model stability, we performed a simulated annealing simulation (Trange:300-500K; Tinc:5K/10ps) in explicit water using NAMD software and CHARMM force field. To validate the method, we run the same protocol to the solved SUN2 C-terminal domain (PDB: 4DXS).

RESULTS & DISCUSSION: After the annealing procedure, the SUN1 N-terminal model results stable as proved by the Root Mean Square Deviation value (9,15±0.52) in equilibration phase. Moreover, the timeline secondary structures proves preserved arrangement during the equilibration phase. By comparison with SUN2 C-terminal domain structure, we can consider the predicted structure as promising model for SUN1 N-terminal domain.

CONCLUSIONS: The implemented protocol for folding prediction returns a promising protein template for further investigations. The proposed model is required for studying the SUN1 N-terminal domain affinity with the NPC structure (in particular with Nup153 protein) and lamina. We are experimentally testing the SUN1-Nup153 binding via Bio-layer interferometry technique. In future work, we will identify the SUN1 N-terminal specific binding sites to investigate the force distribution at nuclear envelope site. We hypothesise that a different grade of affinity modulates the force distribution influencing cell mechanotransduction and fate, both in physiology and in disease.

INTRODUCTION: Cancer cells are characterized by their proliferative potential, ability to metastasize and high degree of plasticity. Increasing evidences support the central role of the mechanical properties of the cellular microenvironment in cell fate. Reducing the rigidity of an adhesion substrate leads to massive death of human SW480 colon cancer cells [1]. Chromatin de-condensation appears as the priming early event in cell reprogramming [2]. Whether chromatin plasticity of cancer cells is influenced by the Young’s modulus of the cellular microenvironment has not been addressed so far.

METHODS: The behavior of SW480 cancer cells was assayed on polyelectrolyte multilayer films with an elastic modulus of 20 kPa (short-hand notation E20) as a selective soft substrate model for cell survival. To highlight the survival process developed by cancer cells, cells that were resistant on E20 were recovered and amplified on supraphysiologically stiff culture glass slides and replated on E20.

RESULTS & DISCUSSION: A first contact with the soft substrate E20 caused massive SW480 cell death by necrosis, whereas about 7% of the cells did survive exhibiting a high level of condensed chromatin (21% heterochromatin). These surviving cells were round with poor motility, and characterized by limited focal adhesions. However, four consecutives hard / soft cycles elicited a strong chromatin de-condensation (6% heterochromatin) in correlation with increase of cellular survival (about 90%), cell spreading, formation of focal adhesions and higher cell motility. Furthermore, cell survival appeared reversible, indicative of an adaptive process rather than irreversible gene mutation(s). This adaptation process was associated with modifications in gene expression patterns. Interestingly, expression of the homeobox gene CdX2 and the nuclear receptor family gene Hnf4α, two major regulators of intestinal homeostasis with tumor suppressor activity was downregulated, as well as stimulation of the Macc 1 gene involved in metastasis.

CONCLUSIONS: At the ultrastructural level, the de-condensed chromatin induced by mechanical means appeared to be very similar to those obtained chemically by trichostatin A or by the molecule CYT296. This work represents a new step towards understanding how cancer cells resist to mechanical stresses. A totally new approach for chromatin de-condensation only based on mechanical properties of the microenvironment without any drug mediation is thus demonstrated.

INTRODUCTION: Collagen, the major component of connective tissues, is frequently considered the first choice for use in 3D printing of tissues and organs. Tissue extracted collagen however suffers from number of problems, including batch-to-batch inconsistency, structural damage to the molecule, allergic response, risk of disease transmission, and exposure to residual components from the source tissue. Recombinant type I human collagen (rhCollagen) was processed from tobacco plants that were genetically engineered to express 5 genes associated with the production of human Type I collagen [1]. The purified, naïve, rhCollagen is superior to tissue extracted material in major characteristics including safety, mechanical properties and biological signaling [2-3].

METHODS: Recombinant type I human collagen was purified in large scale under cGMP conditions. The purified material was modified with photo-reactive molecules to serve as photocurable media in 3D Bioprinting. Specific compositions (BioInks) were designed by formulating the modified rhCollagen alone, or with additional components to match different printing technologies and mimic variety of tissues. The compositions were characterized for physical and biological properties.

RESULTS & DISCUSSION: rhCollagen and it’s modified versions can be used for 3D printing at room temperature thus avoiding the typical gelation of tissue extracted collagen at these conditions. RhCollagen modified with methacrylic groups (rhCollagen-MA) or thiols demonstrated excellent compatibility with different photoinitiation systems at a broad range of wave lengths including 365, 405 and 500nm. The unique viscosity and shear thinning properties of modified rhCollagen allowed the flexibility to formulate BioInks compatible, with or without cells, with the major printing technologies including extrusion, ink-jet, laser and stereolithography. Scaffolds comprised of BioInk compositions including the modified rhCollagen alone, or in combination with natural or synthetic polymers and cross linkers exhibited physical properties matching natural tissues and demonstrated excellent support for cells proliferation and vitality including a series of primary and differentiated human cells.

CONCLUSIONS: These data demonstrate that photo-curable modified rhCollagen can serve well as a major component in many 3D Bioprinting systems where a need to mimic the natural environment including the physical and biological niches is critical.

INTRODUCTION: 3D microfluidic (µF) devices or organ-on-chips provide a more physiologically relevant microenvironment for stem cells to proliferate or differentiate as compared to traditional cell culture methods [1]. Umbilical cord derived stem cells (UMSC) have advantages over bone-marrow or adipose-derived stem cells, such as, no ethical issues, ease of procurement, and collection of large number of cells [2]. Herein, we attempted to compare the osteo-differentiation potential of UMSC with different chemical factors in a collagen type-I-based 3D µF device.

METHODS: 3D PDMS µF device was fabricated using photolithography and replica molding. Human UMSC were differentiated into osteolineage in 3 different platforms – 3D µF device, 3D collagen beads, and 2D 24-well plate – using osteoinduction medium (OIM) containing 10 mM β-glycerophosphate, 100 nM dexamethasone, and 50 µg/ml L-Ascorbic acid. Media were changed every day for µF device and every two days for other controls. FDA/PI, ALP staining, immunofluorescent staining and qPCR were conducted after 1, 7 and 14 days.

RESULTS & DISCUSSION: The PDMS devices fabricated for 3D stem cell culture contain three channels with central channel containing a hydrogel (with cells) flanked by media for cell growth and differentiation. The hexagonal posts provide surface tension to hold the gel without any leakage. Preliminary results in the 2D and 3D groups showed early osteo-differentiation in OIM-treated samples as compared to the control samples exposed to normal medium.

CONCLUSIONS: As the 3D microfluidic device helps in replicating the stem cell differentiation pathway, as also observed in 3D beads in our study, the application potential of the 3D µF device is multi-fold, especially with respect to bed-side testing of mononuclear stem cell fraction of blood for therapeutic purposes.

1Laboratory of Biomechanical Orthopedics, Institute of Bioengineering, EPFL Lausanne, Switzerland 2Regenerative Therapy Unit, University Hospital of Lausanne (CHUV), Lausanne, Switzerland

INTRODUCTION: Careful design of biomaterials properties, cell-scaffold interaction and in vivo like stimulation is required to guide chondrocytes differentiation and facilitate clinical translation of engineered cartilage. Since articular cartilage is a poro-viscoelastic tissue with high dissipative capacity, temperature increase following joint loading could occur [1]. Given this self-heating phenomenon, a customized biomimetic in vitro platform was developed, to study cartilage thermo-mechanobiology.

METHODS: To induce a stable cell-scaffold interaction, we firstly RGD functionalized the developed stiff and fatigue resistance porous hydrogels with recapitulated cartilage mechanical properties. This ligand grafting process was performed in two steps for functional group activation and peptide conjugation while maintaining desired mechanical properties. In addition, a novel and modular home-made bioreactor was designed to apply stress/strain and desired temperature scheme during culture of cell-laden hydrogels while CO2/O2 and humidity levels are maintained. The gradual temperature increase from 32°C (corresponding to knee temperature at rest) to 39°C (after exercise) during cyclic compression was based on the measured in vivo data inside intra-articular region of the knee during jogging [2]. The synergetic or decomposed effects of temperature and loading on human epiphyseal chondro-progenitor (hECP) cells response were then evaluated.

RESULTS & DISCUSSION: Not only cells attachment was enhanced within the RGD functionalized hydrogels in static culture, but also the cells-hydrogel interaction following biophysical stimulus was better preserved. Moreover, a synergetic effect following thermo-mechanical stimulation was observed in upregulation of Sox9, one of the main regulators of chondrogenic differentiation process [3]. In parallel, Twist1 which is known as chondrogenesis inhibitor [3] was significantly downregulated following thermo-mechanical stimulation. The total extracted RNA from samples varied minimally by intermittent thermo-mechanical stimulation contrary to significant decrease of total RNA for standard culture of hECP cells above knee cartilage temperature at rest (37°C vs 32°C).

CONCLUSIONS: Collectively, intermittent thermo-mechanical stimulation as simulation of self-heating phenomenon following joints physical activity can enhance chondrogenesis while maintaining cells metabolism.

What controls endothelial sprouting? Interstitial flow vs. shear stress
N. Salehi-Nik, S.S. Seyedipour, P. Padmanaban, F. Stein, J. Rouwkema

INTRODUCTION: During angiogenesis, endothelial cell (EC) sprouting occurs when select ECs lining a vessel are exposed to stimulatory factors. Growth factor gradient has been proved to stimulate angiogenesis. However, the effect of shear stress on cell sprouting has been controversial [1-2]. Since certain level of media perfusion is required to support cell viability as well as to maintain the stability of the newly formed vascular network, it is necessary to fine-tune shear stress in engineered tissues. In the present study, we investigated the effect of different amounts of shear stress and interstitial flow on EC sprouting with the aim of finding a new approach to control vascular formation in thick engineered tissues.

METHODS: To determine how different ranges of interstitial flow and shear stress modulate sprouting, we developed a microfluidic platform that contains a crinkle line with different angles (Channel 1), a straight line (Channel 2) and a hydrogel channel in between. Both channels 1 and 2 were lined with a monolayer of ECs. Mural cells and ECs were mixed with the hydrogel and filled in the channel between the two EC lined channels. To assess the effect of shear stress on cell sprouting, the pressure drop in different parts of the channel 1 was kept constant. To apply interstitial flow in different directions, positive or negative pressure difference was considered between two channels. Shear stress and interstitial flow profiles were calculated using COMSOL simulation.

RESULTS & DISCUSSION: Biological self-assembling of ECs resulted in tube formation within the hydrogel after one week. ECs lined the channels 1 and 2 started to sprout and connect to the capillary bed based on the amount of shear stress they experienced. High amounts of shear stress restricted angiogenesis. In contrast, low amount of shear stress was suitable to initiate and support ECs sprouting. Interstitial flow was required to direct ECs connection to the capillary bed within the hydrogel, and making perfusable vascular networks.

CONCLUSIONS: Using a microfluidic platform, we found that biomechanical forces at special ranges direct sprout formation and can be used to control vascularization within engineered tissues.

INTRODUCTION: In case of musculoskeletal dysfunction and muscular dystrophy, one of the key problems of replacement cell therapy is availability of autologous cell sources with potential to differentiate in myogenic direction. Mesenchymal stem cells (MSC) are one of the sources of myoblasts during muscle tissue regeneration. Moreover it is known that viability and differentiation potential of MSC are elevated when they are cultured under 3D conditions in the form of cell spheroids. The aim of this work was to study myogenic potential of MSC from alveolar mucosa (MSC-amc) in 2D (monolayer) and 3D (spheroids) culture.

METHODS: To isolate human MSC-amc, we collected the biopsies of alveolar oral mucosa from healthy donors (n=10) after obtaining their informed consent. We used cultures at passages 3-4. Growth culture medium consisted of DMEM/F12 and 20% FBS (HyClone, USA), induction medium contained DMEM low glucose and 2% Horse Serum (BioInd, USA). Spheroids were formed under standard conditions (37°C; 5%CO2) on agarose plates with micro-wells made using 3D Petri Dishes (Microtissue, USA). Appearance of myotubes in 2D culture and dynamics of spheroids’ formation were monitored via live light time-lapse microscopy in Cell-IQ device (CM Technologies, Finland). Cells in monolayer and 7-day spheroids were fixed in 4% paraformaldehyde for immunocytochemical analysis of MyoD, sarcomeric alfa-actin and MEF 2A+2C expression. For in vivo experiments on rabbits allogenic MSC-amc from suspension or in spheroids were injected in injured calf muscles (3*106cell/200mkl 0,9% NaCl). Muscles were studied on 20, 28 and 35 days after operation.

RESULTS & DISCUSSION: In 2D culture after induction or in 40% spontaneously MSC-amc were able to differentiate in myogenic direction. Cells formed multinucleated myotubes and expressed a marker of myogenesis early stages MyoD. In spheroids obtained from MSC-amc by day 7 both in induction and growth culture medium we observed the hallmarks of myogenic differentiation with the formation of muscle tubes. Differentiated spheroids did not contain early progenitor cells, there was no expression of MyoD, but more differentiated well-formed myofibrils with characteristic peripheral nuclei arrangement, expression of MEF and cross-striation, marked by antibodies against sarcomeric alfa-actin were observed. On the model of calf muscle injury suspension of MSC-ams reduced size of scar, whereas spheroids from MSC-amc promoted full organotypic recovery of muscle tissue.

CONCLUSIONS: 3D culturing of MSC-amc in form of spheroids can stimulate effective spontaneous myogenic differentiation maintain tissue-specific functional characteristics over a long period. Spheroids from MSC-amc can become an alternative accessible and less invasive source of myogenic cells in vitro and for cell replacement therapy in vivo.

Pathophysiology of bone resorption, Faculty of Medicine, University of Nantes, Nantes, France

INTRODUCTION: In order to induce an efficient bone formation with human bone marrow mesenchymal stromal cells (hBMSCs) associated to a scaffold, it is crucial to determine the key points of the hBMSCs action after in vivo transplantation as well as the appropriate features of a scaffold.

METHODS: For this purpose, we compared the behavior of hBMSCs, in vivo, by species specific RT-qPCR, immunostaining and histology, when grafted onto two biomaterials allowing different bone potential. To this aim, the cancellous devitalized Tutoplast®-processed bone (TPB) and the synthetic hydroxyapatite/β-tricalcium-phosphate (HA/βTCP) which give at 6 weeks 100% and 50% of bone formation respectively, were chosen. Biomaterial structure was analyzed by micro-computed tomography and Fourier transform infrared spectroscopy.

RESULTS & DISCUSSION: We first showed that hBMSCs adhesion is two times favored on TPB in vitro and in vivo compared to HA/βTCP. Biomaterial structure analysis indicated that the better cell adhesion on TPB is associated to its higher and smooth open pore architecture as well as its content in collagen. Our 6 week time course analysis, showed using qPCR that only adherent cells are able to survive in vivo giving thus an advantage in term of cell number on TPB during the first 4 weeks after graft. We then showed that grafted hBMSCs survival is crucial as cells participate directly to bone formation and play a paracrine action via the secretion of hIGF1 and hRANKL which are known to regulate the bone formation and resorption pathways respectively.

CONCLUSIONS: Altogether our results point out the importance of developing a smooth and open pore scaffold to optimize hBMSCs adhesion and ensure cell survival in vivo as it is a prerequisite to potentiate their direct and paracrine functions.

INTRODUCTION: The aim of vascular tissue engineering (VTE) is the design of responsive, living conduits, with properties similar to those of native tissue. Collagen type I, being the main component of native vessels, is a promising scaffold material for vascular TE owing to its favourable biological properties and to the ability of cells to remodel its matrix. The present work targets the development of collagen precursors functionalized with photo-crosslinkable moieties while preserving the biocompatibility, and to develop collagen-based hydrogel films with tunable mechanical properties.

METHODS: In brief, methacrylated collagen was prepared by reaction of the primary amines of collagen with 0.5 or 1 eq methacrylic anhydride (MeAnH). An ortho-phthalic dialdehyde (OPA) assay was applied to evaluate the functionalization of the collagen precursors. Identification of the biopolymer peptide sequence was performed via mass spectrometry analysis (Orbitrap) along with bioinformatic analysis on unmodified and functionalized collagen precursors. The position of the introduced double bonds was also determined via proteomics. Crosslinked collagen films were characterized in depth in terms of crosslinking efficiency, gel fraction, swelling ratio and mechanical properties using rheology. Potential in vitro cytotoxicity of the functionalized collagen was evaluated using human umbilical vein endothelial cells (HUVECs). Cell viability, proliferation and morphology were examined via indirect and direct in vitro assays.

RESULTS & DISCUSSION: The OPA assay showed that the targeted lysine groups were successfully modified, with a degree of substitution of 85 and 98% for the 0.5 and 1 eq MeAnH, respectively. In addition to the amino acid quantification and localization, the position of the introduced double bonds was found to have a homogeneous methacrylamide distribution throughout the collagen backbones. Rheological measurements confirmed that an increasing number of crosslinkable moieties yields a higher storage modulus (i.e. 4.8 kPa versus 9.3 kPa), due to a higher network density. High gel fractions (i.e. 87 and 91 %) were obtained. The crosslinking efficiency determined via HR-MAS NMR spectroscopy indicated the occurrence of an efficient crosslinking (i.e. 86 and 88% double bonds being consumed during crosslinking). In vitro assays to evaluate cell-biomaterial interactions of the crosslinked hydrogel films indicated an excellent cell viability (i.e. 97% and 94%) and cell adhesion.

CONCLUSIONS: Collagen type I has been successfully functionalized with photo-crosslinkable moieties. The developed collagen precursors have tunable mechanical properties while maintaining biocompatibility.
Validation of the NANT 001 bioreactor system for automated adipose-derived mesenchymal stem cell expansion

INTRODUCTION: Adipose-derived mesenchymal stem cells (ASCs) are an attractive choice for regenerative therapies due to their minimally invasive method of isolation. As with any source, the need for cell expansion to produce therapeutically useful quantities of cells bring challenges. Manual production of stem cells is labor-intensive, expensive and poses a high risk for contamination. The NANT 001 is an innovative bioreactor that has evolved from manual cell culture principles to introduce a high level of automation. This work reports on the validation of this system for the production of ASCs compared with conventional manual expansion processes.

METHODS: ASCs at passage 1 from a healthy donor were suspended in α-MEM supplemented with 10% Fetal Bovine Serum, seeded into either the bioreactor system or Corning 636 cm² CellSTACK culture chambers at a density of 2000 cells/cm² and incubated at 37°C, 5% CO₂. After 24 hours, and when the cells reached 50% and 90% confluency, the monolayer was washed with PBS and the growth media was replaced. Cells were automatically harvested 24 hours after reaching 90% confluence. Three validation runs were performed. Growth kinetics, cell viability, sterility, trilineage differentiation capacity and surface immunophenotype were assessed.

RESULTS & DISCUSSION: Cell growth kinetics and yield from the bioreactor were comparable to those obtained from the manual process. On average, an inoculation of 1.3x10⁶ cells yielded 52x10⁶ cells from the NANT 001 and 55x10⁶ from the manual process in a 6-day expansion. Viability was not affected by the bioreactor process with >95% cell viability recorded from all 3 runs. Supernatants from all cell cultures tested negative for microbial contamination. There were no significant differences in the adipogenic, osteogenic and chondrogenic differentiation propensity of the cells regardless of expansion process. Three validation runs were performed. Growth kinetics, cell viability, sterility, trilineage differentiation capacity and surface immunophenotype were assessed.

CONCLUSIONS: Collectively, these data illustrate the potential of using the NANT 001 bioreactor for automated expansion of ASCs. The risk of contamination is decreased by reducing the use of open procedures. Ongoing work consists of a GMP validation of the system for the expansion of ASCs from the stromal vascular fraction of adipose tissue. Based on these observations, the NANT 001 bioreactor represents an effective option for closed, automated and aseptic manufacturing of autologous cell products for applications in cell therapy and regenerative medicine.
Medical device coatings to mitigate the foreign body response

INTRODUCTION: The foreign body response (FBR) to an implanted biomaterial leads to the formation of a fibrotic capsule. This capsule can disrupt tissue-implant interactions such as those necessary for communication between a nerve cell and an implanted electrode. Human gene-2 relaxin (H2 relaxin) has exhibited anti-fibrotic activity in vivo. A synthetic short-chain soluble peptide, B7-33, mimics the anti-fibrotic actions of relaxin in vivo. Here, we present a method for the incorporation of B7-33 into polymer coatings for medical device applications.

METHODS: Poly(lactide-co-glycolide) (PLGA) and B7-33 were co-dissolved in DMF to the desired concentrations and then applied to 96 well-plates before being placed in a vacuum system to remove the solvent.

An in vitro reporter gene assay for cyclic adenosine monophosphate (cAMP) activity in human embryonic kidney cells stably expressing the relaxin family peptide receptor 1 (HEK-RXFP1) was used to assess B7-33 activity. Surfaces were seeded with HEK-RXFP1 cells and incubated for 6 hours. Cells were then lysed and reporter gene stimulated Beta-Galactosidase activity measured using a colorimetric substrate to evaluate the relative cAMP responses.

RESULTS & DISCUSSION: Figure 1 demonstrates that the PLGA+B7-33 surface coating (red) dose-dependently activates RXFP1 to a similar level as the soluble B7-33 peptide (blue) though with a 10-fold lower EC50. The dried B7-33 control (green), in the absence of PLGA, demonstrates activity akin to the soluble B7-33.

CONCLUSIONS: The cAMP assay offers a validation method for the development of B7-33 peptide coatings. Here, we have demonstrated that a polymer/peptide surface coating can successfully agonize RXFP1 with an equivalent potency to the soluble B7-33 peptide. This result may indeed open the door to the next-generation of anti-fibrotic device coatings.

Figure 1: Dose-response cAMP activity of soluble B7-33, PLGA+B7-33 coating, and dried B7-33 control as a function of ligand concentration.

Unpicking the permanent adhesion of barnacle cypris larvae
N. Aldred

Presenting Author: Nick Aldred, nicholas.aldred@ncl.ac.uk
1School of Natural and Environmental Sciences, Newcastle University, NE1 7RU, UK.

The permanent adhesion of larvae to surfaces represents a pivotal point in the life-cycle of barnacles, as the free swimming organism commits to a sessile existence. While surface selection and settlement by barnacles is clearly of ecological interest, it is also a focus for more applied research into biological adhesives and antifouling. The permanent adhesive of the cypris larva is one of nature’s most impressive but least well understood glues. In the context of marine biofouling, a multi-billion-dollar industry, cyprids and their adhesion are of particular interest as the colonizing stage of barnacles, and arguably more important than the adult form as the target of fouling control strategies. Better knowledge of cyprid adhesion would therefore contribute to the development of coatings that resist barnacle adhesion without the need for biocides. This talk will outline recent progress towards understanding the larval adhesion system including its protein and non-protein components - both lipids and carbohydrates, as well as proteins, are required for successful adhesion. The dynamics of cyprid attachment to surfaces will be discussed, as well as implications for the development of novel fouling-resistant coatings and bio-inspired adhesives.

INTRODUCTION: Regeneration of bone defects by tissue engineering is a challenging field that requires the design of scaffolds with suitable morphological, structural and biocompatible properties. Unlike traditional fabrication technologies, 3D printing enables manufactures with defined pore sizes and geometries, with patient-specific macroscopic shape. We propose 3D printed thermoplastic poly-ether-urethane (TPU) as a scaffold for bone tissue.

METHODS: TPU scaffolds were fabricated by fused deposition modeling (Sharebot 42). Twelve layers were printed in three layer-by-layer patterns at 90°, 45° and 60° relative angle. Morphology, printed filaments dimension and pore size were characterized. Weight variation tests were performed in culture medium at 37 °C. Compressive mechanical properties were tested in wet conditions at 37 °C by Dynamic Mechanical Analyzer. In vitro indirect cytotoxicity tests were performed using L929 cells (ISO 10993). In vitro cytocompatibility and osteogenic differentiation were investigated using bone marrow-derived human mesenchymal stem cells (hMSCs). Metabolic activity of hMSCs was evaluated by AlamarBlue® assay up to 14 days. Histological analysis by Hematoxylin & Eosin (H&E) and von Kossa staining was used to study hMSC morphology and osteogenic differentiation. Data were statistically analyzed by ANOVA.

RESULTS & DISCUSSION: The morphology of the printed scaffolds matched the one of the CAD-designed models, after printing process optimization (Fig. 1). Printed filaments diameter was 600 µm; pore size varied from 0.005 mm² (45°) to 0.1 mm² (90°), with 60% average porosity. Weight variations values were up to 75%; all scaffolds were stable up to 21 days. The compressive modulus ranged in 2–4 MPa, depending on the printed pattern. In vitro cytotoxicity tests proved the absence of cytotoxic effects. An increase of metabolic activity was detected during the culture and osteo-differentiated hMSCs colonized the pores of the scaffolds with mineral ECM deposition (Fig. 1).

CONCLUSIONS: Scaffold morphological and structural properties are suitable for bone tissue regeneration, proving adhesion, proliferation and differentiation of hMSCs.

INTRODUCTION: Osteoarthritis, resulting from cartilage degradation, poses a great financial burden to healthcare providers. Long-term relief is not possible with current gold-standard treatments; thus there is a need for tissue-engineered alternatives. Immobilised Wnt3a can induce asymmetrical cell division in pluripotent stem cells. Human embryonic stem cells (hESC) can yield large numbers of chondroprogenitors, however, the risk of residual pluripotent cells with the potential to form teratomas, presents a barrier to their clinical application. Use of a Wnt platform as a substrate for differentiation may result in a cartilaginous construct with a more homogenous population of chondroprogenitors.

METHODS: A 14-day directed differentiation protocol (DDP) [3] was initiated on hESC. On d4, cells were split and transferred to Wnt3a-modified polycaprolactone (PCL) discs. Acellular fibrin gels were placed on top of cells on the following day and the DDP was completed. Gene expression analysis and immunocytochemistry (ICC) were carried out on d9 and d14 samples. For control samples, bound Wnt ligands were inactivated with dithiothreitol (DTT) before cell seeding. An additional control group of polymers was incubated with 5% BSA instead of Wnt3a.

RESULTS & DISCUSSION: Constructs on the Wnt-modified PCL show significantly increased ACAN expression on d9 compared to BSA controls and significantly increased COLII expression on d14 compared to DTT controls. A migrating population of differentiating cells is more evident in the Wnt3a-modified group (figure 1).

CONCLUSIONS: Use of the Wnt platform, in combination with the DDP, may yield hydrogels with enhanced chondrogenic potential.

Development of a 3D human intestine mucosal model to aspects of inflammatory bowel diseases
N.J. Darling1, S.A Przyborski1,2
Presenting Author: Nicole Darling, n.j.darling@durham.ac.uk
1Department of Biosciences, Durham University, Durham, UK 2Reprocell Europe, Sedgefield, UK

INTRODUCTION: Intestinal epithelial function is assayed using the in vitro industrial standard Caco-2 monolayer. However, this model has numerous limitations including the lack of communication between different cell types and is not readily adaptable to mimic diseased intestinal tissue. We aim to adapt this intestinal model to better recapitulate the native intestine architecture by culturing Caco-2 cells with multiple types of cells, including immune cells, in a three-dimensional microenvironment and hypothesise that this model can be adapted to mimic aspects of inflammatory bowel disease (IBD).

METHODS: Human dermal fibroblasts (HDFn) were seeded onto Alvetex® Scaffold inserts and cultured for 7 or 14 days. After 7 days, differentiated U937 macrophages can be added to the HDFn and cultured for a further 7 days. After a total of a 14 day of HDFn pre-culture period, Caco-2 cells were seeded and cultured for a further 21 days to allow differentiation to occur.

Functional properties of the model were assayed with Transepithelial Electrical Resistance (TEER) measurements and tissue construct morphology was observed by histology, electron microscopy and immunofluorescence.

RESULTS & DISCUSSION: Fibroblasts deposit a rich collagenous extracellular matrix, resembling the lamina propria, within which immune cells integrate into. Co-culture of the stromal compartment with epithelial cells results in the formation of an intact barrier due to the presence of a highly polarised monolayer of differentiated cells. This is evidenced by the columnar appearance of cells in conjunction with the formation of a microvilli brush border.

CONCLUSIONS: The 3D mucosal construct more closely resembles the architecture of the human intestine than previous in vitro models. Data thus far has indicated that the model has improved functional characteristics over the Caco-2 monolayer and is more like in vivo tissue. Future experiments will endeavor to stimulate the immune cells within the model to recapitulate features of IBD.

Figure 1: H&E staining of Caco-2 cells cultured for 21 days on top of fibroblasts cultured for 14 days prior to Caco-2 cell seeding. Scale bar: 50 µm. TEER throughout the 21 day epithelial cell culture of the Transwell insert, co-culture model and the small intestine.

ACKNOWLEDGEMENTS: The authors would like to thank the NC3Rs for funding this project and Reprocell Europe for providing human tissue samples.
Scaffolding and bioprinting via advanced laser technologies
N.V. Minaev

Presenting Author: Nikita Minaev, minaevn@gmail.com

1Laboratory of Laser Nanoengineering, Institute Photon Technologies (IPT), Federal Scientific Research Centre “Crystallography and Photonics” RAS, Russia

INTRODUCTION: In recent years, laser technologies have found wide applications in various fields of medicine and biomedical researches such as plastic surgery, oncology, ophthalmology and others. With the use of laser radiation, it became possible to form scaffolds and tissue-engineering structures with desired properties, and to manipulate of living micro objects, such as microorganisms and cells. This report presents our results in developing of several laser technologies for biomedicine and tissue engineering.

METHODS: Several laser technologies and methods are used to solve some biomedical tasks: - Technologies of single- and two-photon polymerization and surface-selective laser sintering were used for formation of scaffolds from the original biocompatible and bioresorbable materials. - Laser photopolymerization was used for creating an anisotropic structured material based on collagen sponge and photoreactive polylactide. - The LIFT (laser induced forward transfer) printing method has been used to functionalize scaffolds by living cells and cell spheroids. - The method of the laser engineering microbial systems (LEMS) based on the LIFT method was developed.

RESULTS & DISCUSSION: Original photosensitive compositions containing natural polysaccharides (chitosan) and polylactides have been developed. Chitosan scaffolds, fabricated by two-photon polymerization appeared non-cytotoxic and suitable for treating the spinal cord injuries and other neuronal degenerative diseases [1]. Three-dimensional scaffolds with improved hydrophilic and osteoinducing properties were produced using the surface-selective laser sintering (SSLS) method from modified polylactide [2]. LIFT method of the laser printing, was used for moving cartilage cells and cellular spheroids to the surface of the scaffolds. This made possible to build tissue-engineering construction for regeneration of complex skeletal tissues. The LEMS technology has been developed for cultivating of difficultly cultivated or uncultivated microorganisms from soil sources. The ability to obtain a wider biological diversity of microorganisms from the trivial soil, compared with standard methods of cultivation was demonstrated [3].

CONCLUSIONS: The combination of the proposed laser methods and technologies is promising for solving a number of important problems in the field of medicine, tissue engineering and microbiology.

ACKNOWLEDGEMENTS: Financial support was received from by the Ministry of Science and Higher Education within the State assignment FSRC «Crystallography and Photonics» RAS in part of «laser engineering of microbial systems», Russian Science Foundation (Project No. 18-32-20184) in part of «development of laser technologies scaffold formation».

INTRODUCTION: Recent decades have been characterized by advancement of medical implant design to improve the clinical success rate. One of the challenges in the implant field is to develop surfaces capable of controlling and guiding tissue healing. Neovascularization is considered an essential prerequisite to osteogenesis as the mesenchymal progenitors of osteogenic cells have a perivascular origin. Thus, our aim was to examine the effect of nanosurfaces on peri-implant neovascularization and mesenchymal cell recruitment in vivo.

METHODS: We have developed a cranial implant window model to track peri-implant wound healing intravitally over clinically relevant time scales as a function of implant topography [1]. Combined with in vivo cell labeling strategies, it allows direct visualization of neovascularization as well as migration and function of peri-vascular stromal cells in the peri-implant wound site.

RESULTS & DISCUSSION: Quantitative intravital confocal imaging showed that the microvascular density around a nano implant surface (TiNT) was significantly higher than a machined surface (TiMA) at days 7, 11, and 28 post-implantation. Nano surface contributes to the development of a radially arranged vascular structure with hierarchical branches spatially closer to the surface of the Ti-implant. Use of nanosurfaces accelerated the recruitment of perivascular mesenchymal cells (PMCs) that were localized in the periosteum. Microscopic and histological evidence showed that the PMCs were the progenitors of multiple cell types including osteogenic cells. The early population of the peri-implant wound site by PMCs was correlated with the growth of the neovasculature. Further µCT assessment of the bone formation showed that the changes in the rate and pattern neovascularization and mesenchymal cell recruitment resulted in a change in the mechanism of peri-implant bone healing from distance to contact osteogenesis.

CONCLUSIONS: The knowledge gained from the current study informs the design of endosseous implants capable of controlling tissue healing and overcoming delayed peri-implant wound healing as seen in conditions such as hyperglycemia.

INTRODUCTION: The active stages of intestinal inflammation (in Crohn’s and ulcerative colitis diseases) is characterized by intermittent wounding and inflammation in the effected intestinal regions [1,2]. The progress in mucosal/epithelial damage and inflammation causes a decrease in transepithelial resistance and increases the gut permeability [3]. Herein, we report a hyaluronan based hydrogel enema system that protects the damaged gut epithelium by enhancing the tight junction proteins, mucosal repair and helps in maintaining the epithelial gut barrier integrity [Figure 1].

METHODS: A HA-enema scaffolding system was fabricated by embedding high molecular weight (1.1x 10^6) HA particles in a HA hydrogel system. Anti-inflammatory studies of the system were conducted in mouse bone marrow derived macrophages (BMDMs). Human colon epithelial like cells (Caco-2, T-84) were used to test the trans-epithelial electrical resistance (~TEER), permeability effect by transwell assay and tight junction proteins up regulation by western blotting. Further, the system efficacy and barrier integrity were tested in dextran sodium sulphate (DSS) induced colitis mice model, in vivo.

RESULTS & DISCUSSION: HA particles in the hydrogel-enema were found to be 320±100 nm in size (Figure 2A). Cell culture (BMDMs) experiments showed a significant decrease in induced cytokines TNF- α, IL-6 secretions (Figure 2B). Treatment upon Caco-2 cell transwells, HA-hydrogel enema and Naïve HA increased the percentage ~TEER, and decreased the FITC-dextran flux (permeability) compared to LPS treatment (Figure 2C). Up regulation of the gut epithelial tight junction proteins (Cldn-4, Ocldn) were observed after HA-gel enema (100 μg/ml) treatment on Caco-2 cells (Figure 2D).

CONCLUSIONS: These data illustrate the beneficial effect of HA-hydrogel enema in mucosal protection of the damaged gut epithelial and improvements to the intestinal barrier function.

¹Graduate School of Nanobioscience, Yokohama City University, Yokohama, Japan

INTRODUCTION: Multicellular spheroids are thought to be useful for drug screening. However, it was hard to fill extracellular matrices (ECMs) into the spheroids, which improve structures and/or functions of them. For example, Matrigel has a potential to support cell polarity and tubulogenesis. Hyaluronic acid (HA) is detectable around of islets in a healthy condition but internal of them in a diabetic one. We developed a method to fill thin-layered ECMs into the spheroids. In this report, we show results that ECM filling enhanced cell-polarity of the mini-liver, formation of seminiferous tubules of the mini-testis, and producing the diabetic islet having reducing glucose-dependent insulin secretion.

METHODS: We used human hepatoma cell lines Hep G2 and Huh-7 for the mini-liver, mouse (ICR) testis cells for the mini-testis, and mouse (C57BL/6NcrSlc) islet cells for the diabetic islets. When we use hepatoma cell lines, they were suspended in culture medium at 2 x 10⁶ cells/ml. To prepare mouse testis cells, the testes isolated from day 1.5 neonatal mice were digested by collagenase reagents. The testis cells were suspended in culture medium at 1 x 10⁸ cells/ml. In the case of the islet cells, they were prepared at 8 x 10⁶ cells/ml. Spheroids were formed by the methylcellulose method. Methylcellulose was dissolved at 3% into the each medium suitable for the cell type. We injected 1 µl of the cell suspension into the methylcellulose medium. Aggregation of cells was occurred in 10 to 30 min, thereafter, they formed spheroid depending on their adhesion and self-organization properties. The spheroids were cultured for 1 day (the mini-liver and islet), or 2 days (the mini-testis) in the methylcellulose medium, and isolated for additional culture in the normal medium without methylcellulose. Thin-layered ECMs (Matrigel for the mini-liver and mini-testis, HA for the diabetic islet) was filled into the spheroids by dissolving ECM to the cell suspensions. Cells and dissolving ECM were gathered and condensed after injection into the methylcellulose medium. Additional culture was done 1 day for the mini-liver and islet, or 12 days (5 days in normal medium and 7 days in medium with Di(2-ethylhexyl)phthalate (DEHP), a chemical agent showing reproductive toxicity) for the mini-testis. Structures, or protein expression and localization were confirmed by observation of paraffin sections with hematoxylin-eosin staining and immunohistochemistry. Glucose dependent insulin secretion was surveyed by ELISA.

RESULTS & DISCUSSION: The mini-liver with thin-layered Matrigel had improved localization of ZO-1and claudin-1 compared to the normal spheroids without ECM. In addition, localization of MRP2 and formation of bile canaliculi are enhanced. The mini-testis with thin-layered Matrigel showed relatively matured seminiferous tubules and those tubules had sensitivity to the DEHP.

CONCLUSIONS: Thin-layered ECM filling into the spheroids is effective to form high-value-added the mini-organs for drug screening.

INTRODUCTION: There is a common problem in the developing the quality control test of cell therapy products due to the complexity of the mode of action. In this study, we have developed the quality evaluation method concerning about the mode of action of epithelial cell sheet product. The results of traditional evaluation methods (cell number count or cell purity measurement) do not always correlate with the product efficacy. Therefore, we have developed the simple quality control test using qPCR array card to measure the expression levels of critical quality genes. We firstly analyzed the comprehensive gene expression profiles of epithelial cell sheet products which were fabricated in GMP-grade using next generation sequencer (NGS). As a result of NGS analysis, the genes of secretory factors which associate with the mode of action of epithelial cell sheet (enhancement of cell migration, prevention of the inflammatory immune cells infiltration and inhibition of fibrosis) were highly expressed in the epithelial cell sheets in comparison with oral submucosa. We also assessed the in vitro activity of conditioned medium of epithelial cell sheet products for the exerting the therapeutic effect. Next, we validated whether these secretory factors correlated with the mode of action of epithelial cell sheet by in vitro assay and selected the candidate genes on the basis of the result of this validation and the literature research. Finally, we analyzed the gene expression levels of the selected genes in the epithelial cell sheet products by RT-qPCR and determine the expression threshold for the evaluation of epithelial cell sheet quality. In this research, several candidate genes were identified for the evaluation of the quality of epithelial cell sheet product. It is necessary to evaluate the eligibility of these genes for the accurate quality control test by searching the association between the result of the therapeutic effect and the gene expression levels of candidate genes. Our newly developed method enables us to evaluate the product quality more rapidly and accurately than the traditional method. In consequence, our method will contribute the industrialization of regenerative medicine product.

Figure 1: Scheme of the candidate genes selection for quality control test. At first, we analyzed the global gene expression profiles of epithelial cell sheet products. Next, secretory factors associated with the mode of action (MOA) of epithelial cell sheet product were selected.

INTRODUCTION: ADSCs are at the forefront of stem cell therapy due to less invasive isolation procedures and its higher yield in cell number after purification. Growth Factors (GFs) such as Transforming Growth Factor β (TGF-β) and Bone Morphogenetic Proteins (BMPs) have been investigated as effective tools for driving tenogenic differentiation of stem cells. For example, recent studies highlighted the promising effect of BMP-12 in the tenogenic differentiation of ADSCs [1]. Other studies have compared the effect of different GFs in the upregulation of key markers involved in tendon commitment both in ADSCs [2] or other stem cell lines [3]. Herein, we focused on the characterisation and the differentiation potential of human ADSCs in the presence of several GFs in the absence of serum.

METHODS: ADSCs were serum starved and treated with different customised media as the differentiation factor. After specific time points, several techniques were performed: 1) Analysis of messenger RNA (mRNA) for common tendon markers was performed by Real-Time Polymerase Chain Reaction (RT-PCR). Likewise, markers for other cell lineages were analysed. 2) Protein expression was confirmed by Western blotting. 3) Cellular localisation of the markers was evaluated by Immunocytochemistry (ICC) techniques.

RESULTS & DISCUSSION: In this study, we evaluated the tenogenic effect of different GFs on ADSCs. Scleraxis, a transcription factor involved in tendon development, was upregulated at the mRNA level, but the expression was significantly different depending on the GFs used. Collagen type 1, the most abundant type in tendon, was greatly induced. Interestingly, deposition of Collagen I on the extracellular matrix (ECM) by the ADSCs was altered depending on the media used, which was confirmed by ICC. Additionally, cell morphology and confluency changed depending on the GF used.

CONCLUSIONS: Our data suggest that specific environments may be needed for the tenogenic development and potential application for the treatment of the injuries without overstimulation. Overall, we believe ADSCs represent a promising approach for tendon regeneration and repair.

INTRODUCTION: Healthy tissues surrounding abdomino-pelvic tumours may be impaired during radiotherapy and could lead to chronic gastrointestinal complications with substantial mortality. Injection of Adipose-derived Mesenchymal Stromal Cells (Ad-MSC) represents a promising therapeutic strategy. However, many stem cell clinical trials do not confer expected beneficial effect, suggesting a real need to accelerate research towards the successful clinical application. We hypothesized that heparan sulfate (HS)-mimetic injections that restore the extracellular matrix network and enhance the biological activity of growth factors, associated with local injection of MSC protected in a hydrogel that improves cell engraftment and cell survival, could improve the therapeutic benefit of MSC treatment.

METHODS: We used an experimental model of radiation proctitis developed in rats that reproduces severe colonic mucosal damages and fibrosis similar to those observed in patients treated by radiotherapy [1]. We tested injections of HS-m, local injection through endoscopy of Ad-MSC embedded in Si-HPMC hydrogel as well as combinations of these various treatments. The therapeutic benefit was evaluated by endoscopy, histology and functional parameters as epithelial barrier were also tested.

RESULTS & DISCUSSION: We demonstrated that hydrogel loaded-Ad-MSCs were viable, able to secrete trophic factors and responsive to the inflammatory environment. In animal model, Ad-MSC+Si-HPMC improve colonic epithelial structure and hyperpermeability compared with no embedded cells. This therapeutic benefit is associated with greater engraftment of Si-HPMC-embedded Ad-MSCs in the irradiated colonic mucosa [2]. We also demonstrated that combination of HS-m to hydrogel-embedded MSC treatment enhances the therapeutic benefit of MSC therapy alone. Indeed, for the first time, a decrease of the injury score in the ulcerated area was observed. We also demonstrated that the combined treatment favored the epithelial regenerative process. Finally, using an animal model of colonic surgery after irradiation, we demonstrated that the combined treatment improved rat survival, healing of the anastomosis and scar quality assessed by collagen deposit [3].

CONCLUSIONS: In this study, we identified a new way, clinically applicable, to optimize stem-cell therapy and could be proposed to patients suffering from severe colonic defect after radiotherapy.

Effective vascularization and efficient bone formation in osteogenic grafts requires VEGF dose control

INTRODUCTION: Spontaneous vascularization of large-size bone grafts based on bone marrow-derived mesenchymal stem cells (BMSC) is insufficient and requires therapeutic stimulation to ensure progenitor survival and bone formation. However, sustained VEGF over-expression from genetically modified BMSC leads to excessive osteoclast activation and bone resorption. Recently, we found that short-term delivery of recombinant VEGF protein cross-linked in fibrin hydrogels could prevent osteoclast recruitment while ensuring increased vascularization. Here we investigated the role of VEGF dose on the coupling of angiogenesis and osteogenesis, in order to define a VEGF therapeutic window for vascularized bone grafts.

METHODS: Recombinant VEGF was engineered with a transglutaminase substrate octapeptide (TG-VEGF) to allow cross-linking into fibrin hydrogels. Osteogenic constructs were prepared with human BMSC and hydroxyapatite granules in a fibrin hydrogel containing different TG-VEGF concentrations (none, 0.1, 1, 10 and 100 µg/ml).

RESULTS & DISCUSSION: All TG-VEGF doses increased vessels density up to 5-fold already after 1 week and vascularization persisted at all later time points. However, vascular in-growth reached up to 30% of the construct area in grafts with 0.1 µg/ml of TG-VEGF, whereas higher VEGF doses significantly reduced invasion by blood vessels (Fig. 1). A deeper vascular invasion in the 0.1 µg/ml condition improved human cell survival and proliferation up to the core of the graft. After 4 and 8 weeks, bone tissue development was enabled by 0.1 µg/ml of TG-VEGF as efficiently as with naive BMSC alone. Grafts with 0.1 µg/ml of TG-VEGF also contained significantly more mature bone tissue than all other conditions. In contrast, higher VEGF doses progressively impaired bone formation, in correlation with increased osteoclast recruitment and decreased progenitor differentiation, marked by human bone sialoprotein (BSP).

CONCLUSIONS: These data suggest that VEGF effects on promoting vascularization and bone resorption are dose-dependent and that a therapeutic window exists that enables both rapid vascularization and efficient bone formation. Factor decoration of fibrin matrices provide a clinically applicable strategy, comprising no genetic modification, homogeneous and tunable factor doses and limited and controllable duration of factor delivery.
**SmartCaP™: A next generation pro-angiogenic fibrin-based bone void filler**

**INTRODUCTION:** Autografts are the standard choice of treatment for bone defects. However, their use is limited by disadvantages such as limited availability, donor-site morbidity and the risk of infection¹. There still exists an unmet clinical need for novel bone graft substitutes that can eliminate the use of autografts. One of the main issues with current bone graft substitutes is their lack of or limited angiogenesis, which is fundamental to bone regeneration. We have developed a novel off-the-shelf, osteogenic and pro-angiogenic scaffold branded SmartCaP™ to act as a bone void filler.

**METHODS:** SmartCaP™ comprises mainly fibrin in the form of a fibrous sheet, coated with intermediary precursor bone mineral phases of calcium and phosphate. SmartCaP™ was characterised using SEM, EDX, FTIR, Micro-CT, Mercury intrusion porosimetry and von kossa histological staining. Angiogenesis was tested using ex ovo CAM assays. MC3T3-E1 mouse pre-osteoblasts and human MSCs were seeded onto SmartCaP™ under osteogenic and non-osteogenic conditions over 28 days. Cell viability, proliferation and osteogenic differentiation was assessed using standard assays.

**RESULTS & DISCUSSION:** SEM analysis revealed that SmartCaP™ is a homogeneously porous structure comprising of a wide pore size range with an average porosity of 89%. EDX, FTIR, Micro-CT and von kossa staining confirmed the deposition of calcium and phosphate precursor phases within the biomaterial. CAM assays showed that SmartCaP™ is pro-angiogenic and supported the infiltration and growth of blood vessels. SmartCaP™ supports the growth and proliferation of MC3T3-E1 and human MSCs as well as their osteogenic differentiation, which is more marked under osteogenic conditions.

**CONCLUSIONS:** The data suggests that SmartCaP™ is osteogenic, osteoconductive and biodegradable. Therefore, it can act as a template to regenerate bone naturally over time. Due to the physical nature of SmartCaP™, it can be easily manipulated by the surgeons in the clinic. The future work is to test SmartCaP™ in an ovine model of cancellous bone defects. The use of such a biomaterial would eliminate the need for a second surgery to harvest autografts, significantly reducing costs and surgery times.

INTRODUCTION: Rheumatoid arthritis (RA) is a chronic inflammatory autoimmune joint disease. There is no cure for RA. Novel biological therapies have revolutionised the management of RA. However, up to 30% of RA patients fail to respond to currently available biological therapeutics and 50% of those prescribed the treatment discontinue use after 2 years [1]. Mesenchymal stem cells (MSCs) possess anti-inflammatory and immunosuppressive properties that may be exploited therapeutically [2]. Extracellular vesicles (EVs) are a heterogeneous group of small membrane vesicles with key roles in cell-to-cell communications, cell signalling and immune response modulation [3]. In this project, we tested the therapeutic potential of EVs in the antigen-induced arthritis (AIA) model of inflammatory arthritis.

METHODS: EVs were isolated from conditioned medium of human bone marrow MSCs by differential ultracentrifugation. Identification of EVs was achieved using a flow cytometric analysis (MACSPlex human exosome detection kit, Miltenyi) and transmission electron microscopy. Tunable Resistive Pulse Sensing Technology from IZON Science was used to measure the size of isolated EVs. AIA was induced in pre-immunised animals by intra-articular injection of methylated BSA and EVs were injected intra-articularly 1 day post arthritis induction. Control animals were injected with EV-depleted medium. EVs effect on T cell proliferation was assessed in co-cultures.

RESULTS & DISCUSSION: The positive confirmation of tetraspanin proteins CD9, CD63, CD81 was achieved by flow cytometry. The size of isolated vesicles ranged from 159 to 290 nm and the mean size and standard deviation was 198.0 ± 44.7nm. Morphological evaluation of isolated EVs revealed a consistent sphere shape of vesicles. Analysis of knee diameter as a measure of swelling showed significant reductions both 2 and 3 days post-induction of arthritis compared to control injected animals. EV-treated mice revealed a significant reduction in cartilage depletion and arthritis index, representing overall disease severity, compared to control-treated mice at day 3. EVs decrease IL-17a expression in CD4+ cells.

CONCLUSIONS: The results demonstrate a clear beneficial effect via injection of EVs into the inflamed joint. We propose EVs as a potential therapeutic approach for the treatment of inflammatory arthritis. Further studies are required to identify the molecular properties of EVs responsible for their therapeutic effects.

INTRODUCTION: Despite numerous studies and discoveries in the field of the correction of diffuse liver diseases, the search for pathogenetic therapy of liver cirrhosis (LC) remains relevant today. It is known that the use of platelet-rich plasma (PRP) leads to rapid tissue repair, being one of the most promising alternatives in regenerative medicine.

METHODS: The experiment was conducted on adult male Wistar rats weighing 160-180 g, n = 50, including 10 intact animals. The following groups were singled out: I - control - animals with stimulated LC without correction, n = 20; II - rats with stimulated LC with PRP correction, n = 20. The pathology was modelled by intragastric administration of CCl₄ at a concentration of 50 % with replacement of drinking water with a solution of ethyl alcohol at a concentration of 10 %, for 120 days. The first day of PRP administration was considered the first day of the experiment. Percutaneous injection of PRP in a dose of 0.1 ml was carried out twice with an interval of 7 days. Animals were removed from the experiment on the 15th and 30th day after the last administration of PRP. Were conducted a complete blood test (GBT), biochemical studies of the activity of liver enzymes (ALT, AST) and pathological examination under a Leica DLMS light microscope, according to standard techniques.

RESULTS & DISCUSSION: In group I, on the 120th day it was revealed: GBT - the levels of erythrocytes and hemoglobin are reduced relative to the intact group - erythrocytes 3.4 ± 0.26 million, hemoglobin 107 ± 0.18 g/l; ALT activity was 4.5 times higher - 8.2 ± 0.41 units/l; AST 3.5 times higher - 4.82 ± 0.56 units/l (p˂0.05). Histologically: violation of the histoarchitecture of hepatic tissue, expressed hyperemia, bilirubinostasis, hydropic degeneration, foci of central lobular necrosis, lympho-histiocytic infiltration with expansion of portal tracts, foci of a false and full sept formation, intralobular proliferation of connective tissue, expressed vascular sclerosis – the formed cirrhosis.
In group II, on the 15th day the cytological syndrome persisted: ALT activity was 3 times higher - 6.7 ± 0.37 units/l, AST activity was 115 % higher - 2.8 ± 0.29 units/l compared to the intact group (p˂0.05). Histologically: the discomplexion of the hepatic beams, severe protein degeneration, areas of bridging necrosis, dilated portal tracts, anemic vessels, areas of perivascular fibrosis with areas of hyalinosis. In group II on the 30th day, it was revealed: GBT – within the normal range; ALT activity was higher by 62 % - 2.75 ± 0.35 unit/l, AST activity was 46 % higher - 1.9 ± 0.42 units/l in comparison with the intact group (p˂0.05). Histologically: intact structure of hepatocytes, the presence of protein dystrophy, extended portal tracts with venous plethora, and mild vascular fibrosis.

CONCLUSIONS: On the 120th day of intragastric administration of CCl₄, an LC experimental animal was formed. In group I of experimental animals without PRP correction, manifestations of liver cirrhosis for all studied parameters remained during experiment. In group II, both on the 15th and 30th day after the last injection of PRP, there was a tendency to a decrease in the activity of hepatic enzymes, and the histological picture was characterized by normalization of the structure of hepatocytes, a decrease in the manifestations of inflammation and fibrosis. The use of PRP in LC has positive effect on the functional activity of hepatocytes and restoration of liver histoarhecture in rats.
Study of true morphological structure of macroporous hydrogel scaffolds using SEM and LSCM – Impact to cell growth

INTRODUCTION: Porous hydrogels are widely used as scaffold templates in tissue engineering. The connectivity and architecture of pores are one of the major factors governing the cell behaviour, such as cell attachment, proliferation and migration. The scanning electron microscopy (SEM) is the most frequently technique to visualize architecture in hydrogels. The scaffold samples have to be freeze-dried for SEM. This preparation step can affect the morphology of hydrogel porous structure. Moreover, the freezing itself can greatly differ in dependence on freezing media, freezing velocity etc. Also the absence of water in hydrogels can damage the sample, above all it deforms pores, and influences pores distribution. The efficient way how to avoid these phenomena is the use of laser scanning confocal microscopy (LSCM). LSCM observing the hydrogels in their native state and allows fast assessment of hydrogel pore size distribution in the hydrated state. Moreover, LSCM enables in-situ observation of hydrogels with growing cells.

METHODS: Porous hydrogel were prepared by thermally initiated free radical polymerization of the (N-(2-hydroxypropyl) methacrylamide) (HPMA) monomer. Salt particles served as porogen. SEM were performed using TESCAN Vega PLUS TS 5135 microscope. Samples were prepared using freezing in -23°C, -78,5°C or -157,9°C. LSCM were performed using Olympus laser scanning microscope FV10-ASW. The 3D computer reconstruction was done using the Software package MIMICS 8.13. Rat mesenchymal stem cells (rMSC) were cultivated in scaffolds for 5 days and cell growth were visualized by LSCM.

RESULTS & DISCUSSION: The porous non-degradable hydrogels based on covalently cross-linked poly(HPMA) were prepared. We correlated the gel morphology obtained from LSCM vs. that obtained by SEM with various freeze-transcriptional OCT-4, SOX-2, NANOG and drying cycle parameters. The tested hydrogels were made with three different sizes of porogen (0-30um, 30-50um, 50-90um). The resulting pore sizes in gels were determined from SEM images and compared with those obtained from LSCM scans. The computation 3D modelling was used to calculate pore volume and pore size distribution from LSCM pictures. Finally, the rat mesenchymal cell cultivation and growth studies were performed with all hydrogels types to evaluate the effect of hydrogel porosity architecture.

CONCLUSIONS: The LSCM is presented as a fast and useful method for real pore size distribution determination without altering the morphology of hydrogel in contrast to the SEM evaluation that revealed significant influence of the freeze-drying step. Moreover, the LSCM offered the possibility of in-situ monitoring the 3D scaffold morphology and visualization of rMSC attachment and growth in dependence of pore size.

INTRODUCTION: Known limitations of autologous chondrocyte implantation (ACI) are the invasiveness of tissue harvesting and a need for two surgical procedures. In addition, known issues are fibrocartilage formation and de-differentiation of chondrocytes during cell expansion. Alternative cell sources such as adipose-derived stem cells from the soft tissues around the knee joint may offer alternative cell sources, while the patient’s blood derivatives can be utilized in cell culture. The aim of the present study was to investigate the potential of adipose tissue sources and blood serum derivatives for chondrogenic and osteogenic cell culture.

METHODS: Tissue from three fat locations (i) infrapatellar fat pad (Hoffa), (ii) subcutaneous fat and (iii) distal femur/pouch were harvested from three donors during a routine surgical procedure under ethics approval. The tissue was minced with scalpel and digested in collagenase solution. After filtration and centrifugation, cells were cultured to confluence in standard growth media. The expression of specific surface markers for adipose stem cells were analysed by flow cytometry. Blood products platelet-rich plasma (PRP) and hyperacute serum were prepared from the whole blood of healthy donors. PRP was generated by two centrifugation steps in the presence of anticoagulants EDTA or sodium citrate whereas hyperacute serum was produced using the hypACT auto device according to the manufacturer’s protocol. We investigated the proliferative potential of stem cells from different fat sources, supplemented with blood-derived products, using the XTT metabolic activity assay. We induced osteogenesis and chondrogenesis with differentiation media further supplemented by either PRP or hyperacute serum. Differentiation was evaluated by alizarin red and alcian blue staining, gene expression patterns were determined by PCR at day 0, 10 and 21.

RESULTS & DISCUSSION: We observed a highly proliferative effect and enhancement of osteogenesis by hyperacute serum and citrate-PRP, while supplementation with EDTA-PRP or fetal calf serum were less effective. Highest cell viability and chondrogenic / osteogenic differentiation potential was achieved with Hoffa stem cells compared to cells from other fat tissue sources. After evaluation of chondrogenic differentiation, preliminary data revealed better potential of Hoffa stem cells supplemented with PRP with EDTA.

CONCLUSIONS: These preliminary data illustrate potentially beneficial effects of blood-derived products on the regenerative potential of adipose-derived stem cells in cartilage replacement. Choice of anticoagulants affects the biological activity of PRP, which further supports the use of non-anticoagulated serum supplementation instead. All three fat locations can be considered as cell sources, however, best osteogenic and chondrogenic potential was observed with Hoffa stem cells.

ACKNOWLEDGEMENTS: We would like to thank our clinical partners from Evangelic Hospital Vienna for providing the tissues.
Engineering immunomodulating scaffolds by modulating particle size

INTRODUCTION: Macrophages play a key role in tissue regeneration1 and understanding their interaction with biomaterials used in tissue engineering applications is crucial to determine the success and longevity of biomaterial implants. We have previously demonstrated that micron sized HA particles directly promote M1 polarization in primary human macrophages2. The objective of our research is to elucidate the macrophage phenotype induced by micro and nano sized HA particles in vitro and in vivo and to determine whether macrophage phenotype and innate immune cytokines can influence bone tissue regeneration.

METHODS: For in vitro studies primary human macrophages were isolated from healthy blood as described previously 2 and treated with HA particles of different sizes. Immune cell profile and macrophage phenotype was determined by ELISA, Flow cytometry, RT-PCR and Western blot. For in vivo studies, a rat femoral defect model was used to assess immune cell subsets, macrophage phenotype and tissue regeneration post implantation of HA functionalized scaffolds.

RESULTS & DISCUSSION: Treatment of macrophages with nanoHA particles drove robust expression of the M2 markers, CCL13, CD206 and CD163 and specifically enhanced secretion of the anti-inflammatory cytokine IL-10. Furthermore, conditioned media from nanoHA treated macrophages enhanced expression of BMP2 and ALP and mineralization in MSCs in an IL-10 dependent manner. In our in vivo bone model, the presence of nanoHA functionalized scaffolds at the defect site was associated with reduced numbers of inflammatory T cells and neutrophils compared to micron sized HA functionalized scaffolds, while numbers of cells expressing the M2 marker CX3CR1+ increased compared to micron HA functionalized scaffolds. Analysis of functional tissue recovery revealed enhanced mineral deposition in the nanoHA group and the presence of vWF expressing vessels.

CONCLUSIONS: We demonstrate that nanoHA particles are inherently anti-inflammatory and supportive of osteogenesis. Furthermore, we demonstrate for the first time, a novel pro-osteogenic role for the anti-inflammatory cytokine IL-10. The data herein offers compelling evidence that positions nanoHA as a prospective immune-modulating implant material that may be superior to larger particles for use in bone regeneration and may avoid the need to exogenously load cytokines into biomaterial constructs.

INTRODUCTION: Osteointegration is crucial for implant success. Bone morphogenetic protein 2 (BMP2) biomolecules (protein and nucleic acid) have been used with various biodegradable natural and synthetic polymers such as polylactides and fibrin to enhance bone healing in vitro and in vivo [1-2]. Transcript therapy using chemically modified mRNA (cmRNA) is an emerging alternative for local gene therapy resulting in efficient protein production. In this study, we aimed to utilize this technology to create BMP2 coating for Titanium (Ti) implants. For this, diverse strategies were investigated to produce different coatings. We evaluated the effect of coating type and composition on transfection efficiency, kinetics and cell viability in vitro.

METHODS: Ti etching was done using different acids and etching times. Characterization was performed by SEM. Physical adsorption (MetLuc cmRNA-Ti) was done by air drying solutions of different concentrations of Metridia Luciferase (MetLuc) cmRNA lipoplexes on all plain Ti surfaces. Best etching conditions and cmRNA concentrations were selected for further studies. Polylactide and Fibrin coating (MetLuc cmRNA-PDLLA and -Fb): Furthermore, different concentrations of PDLLA (3, 2, 1, 0.5, 0.25 µg/well) and Fibrin (thrombin to fibrinogen final coating ratios: 1, 0.5, 0.25, 0) were used to produce further coating, by adding MetLuc cmRNA to the solutions and allowing the deposition on Ti surfaces. For Fibrin, Tissucol® was used. In this case, fibrinogen was mixed with the MetLuc lipoplexes and subsequently thrombin was added at different ratios. The coated Ti surfaces were freeze dried. Evaluation of transfection efficiency and kinetics, cell viability, and cell proliferation were done using NIH3T3.

RESULTS & DISCUSSION: Our results showed a positive transfection of MetLuc cmRNA of cells seeded on all tested Ti coatings. Interestingly, the lowest transfection efficiency was obtained when MetLuc cmRNA was allowed to dry on plain Ti. A significant improvement was obtained on PDLLA coated Ti surfaces and the best results were obtained for Fibrin coated Ti. In this case, Fibrinogen-coated samples (i.e. MetLuc-F coating ratio of 0) showed the highest results in terms of transfection efficiency. Cell viability and proliferation decreased on transcript activated Ti surfaces (p>0.05). However, this improved significantly by PDLLA and Fibrin coating. Interestingly, fibrinogen alone (no thrombin) performed significantly better than Fibrin in terms of transfection efficiency.

CONCLUSIONS: Our obtained results highlight fibrinogen as a promising candidate for transcript therapy using coatings of Titanium implants.

INTRODUCTION: Intracranial aneurysms are a major health concern and affect 3.2% of the population [1]. Current treatments, open clipping surgery and endovascular treatment, present the drawbacks of invasive surgery and short term efficiency, respectively. The use of a photoactivated hydrogel has the potential to act as an aneurysm filler due to their suitable biological and mechanical properties. Swelling is an important feature of hydrogels and has to be controlled in order to avoid oversizing and overpressure into the aneurysm.

METHODS: 10 wt% polyethylene glycol dimethacrylate (PEGDMA) hydrogels were synthesized using two molecular weights (6 and 20 kDa) and photo-polymerized using 405 nm illumination. Hydrogels swelled in PBS at 37°C and 5% CO2. Swelling ratio was measured in a semi-confined mold, to simulate the blood contact only at the aneurysm neck. Swelling pressure was also determined using a confined compression test. Moreover, critical swelling pressure for aneurysm rupture will be estimated by a computational model. Digital image correlation (DIC) will also be performed to assess the strains on the aneurysm wall, using 3D printed PDMS aneurysm models.

RESULTS & DISCUSSION: Swelling ratio and pressure have a different influence according to the molecular weight of PEGDMA. The swelling ratio increases when the molecular weight is higher. Moreover, the size of the 20 kDa PEGDMA hydrogels was multiplied by 3 in every direction, inducing that the hydrogels get out from the semi-confined mold. The molecular weight has less influence on the swelling pressure, ranging from 169 to 248 kPa. The maximum swelling pressure was obtained for the mixing of 6 and 20 kDa hydrogels.

CONCLUSIONS: 6 kDa PEGDMA hydrogels combine low swelling ratio and pressure, which would be appropriate to act as a filler for intracranial aneurysms. However, the simulation of blood flow into 3D printed aneurysm model using DIC will allow to estimate more accurately the swelling behavior of the hydrogels.

INTRODUCTION: Angiogenesis is needed in almost any regenerated tissue in the body. So far, many strategies have been followed to introduce the proper angiogenic signaling to control endothelial cell fate and create feasible blood vessels that colonize 3D scaffolds. However, even though their efficiency has been probed, this route implies the use of different biomolecules that have some drawbacks such as cost-efficiency ratio, storage difficulties, and a poor understanding of undesired side effects. An alternative is presented here where stimulation by calcium ions enables the cells to control their own signals, reducing side effects [1-2].

METHODS: Angiogenic nanoparticles were prepared by the sol-gel method. Nanoparticles were combined with different scaffolds prepared and optimized by 3D extrusion printing. Nanoparticles were combined with polylactic acid (PLA) as the biodegradable polymer for an ion-releasing platform. Different characterization assays were carried out to assess the microstructure and biological characterization: SEM, mechanical compression assays, ion release, pH, degradation, adhesion and proliferation with hMSCs, tubulogenesis assays using hHUVECs, and the chicken CAM assay.

RESULTS & DISCUSSION: MSCs adhered, colonized and proliferated on the prepared 3D printed scaffolds. Measured calcium ion release had a correlation with the VEGF expressed by the MSCs. HUVECs were stimulated by this VEGF to form tubes. CAM preliminary assays also showed a higher increase of blood vessel formation and colonization inside calcium-releasing 3D scaffolds.

CONCLUSIONS: The production of 3D scaffolds combining high calcium release nanoparticles and PLA was possible. The correlation between calcium release and VEGF (among others) confirmed calcium as a promising low cost pro-angiogenic strategy.

INTRODUCTION: The extracellular matrix provides the necessary cues at micro and nano-scale for cell adhesion, alignment, proliferation and differentiation. Ultrafast pulsed laser irradiation is considered as a simple and effective microfabrication method to produce structures controlling the structure geometry and pattern regularity1. Such structures characterised with an anisotropy discontinuous topographical nature could enhance neuronal growth and alignment2. Soft lithography has been successfully used to transfer well-defined micro-sized patterns from silicon to surfaces of biomaterials allowing the recreation of controlled microenvironments and an in depth study of the influence of surface properties on cell behavior3.

METHODS: In this study, a series of micro-patterned silicon (Si) and titanium composite structures were fabricated by using the ultrashort laser irradiation at a range of fluences, resulting in different patterns. Positive replicas on different concentrations of biodegradable polymers have been successfully reproduced from the Si structures via soft lithography. The morphological characterization of the polymeric replicas was performed by Scanning Electron Microscopy (SEM). The cytocompatibility of replicas with mouse SW10 cell line and mouse Mesenchymal Stem Cells C57BL/6 was evaluated. Immunostaining protocols assessed the cell viability (nucleus – DAPI), cell adhesion and alignment (Cytoskeleton-Phalloidin/actin), focal adhesion points (Vinculin), and early stages of differentiation (ALP Assay).

RESULTS & DISCUSSION: Figure 1: Establishment of focal adhesion on different cell types and substrates. Vinculin is shown in green on the MSCs adhered on Ti film, (right) and on the SW10 cells on Si structure (left).

CONCLUSIONS: All the topographies supported the cells’ adhesion and in particular focal adhesion establishment and maturation. The surface roughness had an effect on the MSCs differentiation. Cell type played a significant role in the above findings.

INTRODUCTION: Human amniotic membrane (hAM) is the innermost layer of fetal membranes, which surrounds the developing fetus and forms the amniotic cavity. hAM and hAM-derived cells possess unique properties that make them excellent candidates for use in clinic, such as low immunogenicity, promotion of epithelization, anti-inflammatory and antimicrobial properties as well as angio-mudulatory, anti-fibrosis and anticancer properties. We examined the effect of human amniotic epithelial cells-conditioned media (hAECs-CM) on cancerous cell lines proliferation.

METHODS: Human placentas were obtained at term pregnancy during Caesarean sections from mother with negative results for HIV-I, and hepatitis B and C. hAM was separated from the chorion by peeling and washed extensively with cold PBS. The epithelial cells were isolated enzymatically. The cell pellet was resuspended and cultured. Medium was changed once after the density of cells reached 85% confluency, and hAEC-CM was collected while cells were growing exponentially. The hAEC-CM was filtered, and used in subsequent experiments. Four different cancer cell were seeded in 96-well tissue culture plates. After 24h the culture medium was exchange with different dose of hAEC-CM. After 48h of the incubation, cell viability was determined by the MTT assay.

RESULTS & DISCUSSION: Data on mitochondrial activity obtained from the optical density of cell culture plates of the experimental groups were transformed in percentages in relation to the control group, considered to be 100%. Different volume of hAEC-CM (50, 100, 150, and 200 µl) reduced the viability of cancerous cell lines significantly in comparison with control group (p<0.05). The maximum reduction was observed in the samples with 200 µl of the supernatant. The hAEC-CM was filtered, and used in subsequent experiments. Four different cancer cell were seeded in 96-well tissue culture plates. After 24h the culture medium was exchange with different dose of hAEC-CM. After 48h of the incubation, cell viability was determined by the MTT assay.

CONCLUSIONS: Our results indicated that hAECs-CM is able to inhibit the proliferation of the cancer cells concentration-dependently. Taken together, these results provide strong evidence that hAECs-CM can be used as a safe and effective cancer-targeting cytotherapy for treating breast and cervical cancer.

INTRODUCTION: The bottom-up realization of three-dimensional (3D) hybrid structures composed of both biomaterials and cells are one of the most interesting and novel approach for in vitro and in vivo tissue regeneration. Biocompatible and biodegradable polymers are essential elements of these bottom-up approaches. They serve as template structures for cells adhesion, proliferation and 3D assembly. Such 3D bio-hybrids have been used as possible models to study on cells differentiation and tissue vascularization. Nevertheless, there are limited studies in this regard. This study focuses on the development of a bottom-up approach enabling the construction of highly complex and precisely designed bio-hybrids by means of the ordered assembling of cell-laden micro-scaffolds.

METHODS: Porous PCL and PLGA micro-scaffolds were fabricated by fluidic emulsion/solvent evaporation technique. The morphological and structural properties of micro-scaffolds were characterized by scanning electron microscopy (SEM) and Micro-CT analysis. Then the micro-scaffolds were arranged into precisely designed layered structures and seeded with cells for the growth of the hybrid tissue. Human dermal fibroblasts were used as model cells to study of micro-scaffolds biocompatibility and tissue formation. The morphology and cell/ECM composition of bio-hybrids were assessed by SEM, immunofluorescence analysis and histology.

RESULTS & DISCUSSION: The SEM and Micro-CT results of micro-scaffolds evidenced a highly porous morphology and structure with proper pores interconnectivity. The in vitro biocompatibility tests showed that micro-scaffolds are biocompatible, enabled cells adhesion and proliferation as well as promoted the formation of hybrid self-supporting structures (Figure 1).

CONCLUSIONS: This study demonstrated that the proposed approach enabled the design and building cell/micro-scaffold hybrid systems with highly oriented pores suitable to promote and guide blood vessels formation in vitro and in vivo.

INTRODUCTION: Tissue engineering strategies aim to repair and regenerate the damaged tissue. Oxygen deprivation and oxidative stress is a key regulator in number of pathological conditions such as inflammation, chronic wound healing, cardiovascular diseases such as myocardial infarction. We herein describe a novel biomaterial-based approach to attenuate oxidative stress and deliver oxygen at the damaged tissue site, thus alleviating tissue repair and regeneration.

METHODS: Antioxidant polyurethane PUAO was synthesised and characterised for biocompatibility and antioxidant potential. Oxygen releasing PUAO-CPO scaffolds were fabricated by incorporation of calcium peroxide in PUAO cryogels. Oxygen releasing cryogels were characterised for oxygen releasing capacity, biocompatibility, attenuation of free radicals and enhancement of cell survival by live/dead and MTT assay under hypoxia conditions. The effect of oxygen releasing cryogels to increase tissue survival under in-vivo ischemic conditions was evaluated in a mice skin flap model.

RESULTS & DISCUSSION: PUAO scaffolds were biodegradable, biocompatible and mechanically elastomeric in nature. In an in-vitro oxidative stress model system, PUAO could reduce intracellular oxidative stress significantly and can combat the menadione as well as ischemic reperfusion induced cell death in cardiomyocytes [1]. PUAO-CPO cryogels showed a sustained release of oxygen upto 10 days. Under hypoxia conditions, H9C2 cardiomyocytes have increased metabolic activity on oxygen releasing PUAO-CPO scaffolds compared to non-oxygen releasing scaffolds [2]. Similarly, H9C2 cells showed increased viability on PUAO-CPO scaffolds under hypoxic environment thus corroborating metabolic activity results. Under in-vivo conditions, antioxidant scaffolds delayed tissue necrosis whereas, oxygen releasing scaffolds prevented tissue necrosis and increased the tissue viability in severely ischemic conditions.

CONCLUSIONS: Collectively, these results demonstrated the feasibility of these scaffolds for regeneration of tissues where lack of oxygen and oxidative stress is a concern. This is an important outcome as this will pave way for development of next generation scaffolds for treatment of diseases like MI and chronic diabetic wound healing etc., where oxygen deliver is a limitation and oxidative stress is a major concern. Future studies will look into preclinical evaluation of these scaffolds in the treatment of diseases such as myocardial infarction and chronic and diabetic wound healing.

INTRODUCTION: Osteoarthritis (OA) is a major musculoskeletal disease characterized by the destruction of the articular cartilage [1], which simultaneously promotes a chronic inflammatory environment that lead to the further progression of the disease. Currently, OA treatments include the intra articular administration of corticosteroids, such as dexamethasone, which decreases the inflammatory environment of OA, but shows adverse effects on tissue healing [2]. Beta-Lapachone (βLap) is a natural substrate of the NADH: quinone oxidoreductase 1 (NQO1) with well-known antitumoral activity. Recently, its therapeutic action for the treatment of fibrosis and pulmonary inflammation has also been reported [3]. The objective of this work is to evaluate the effect of βLap on the inflammatory environment and cartilage metabolism in an ex vivo model of OA.

METHODS: Human cartilage explants (disks of Ø = 6mm) were obtained from OA patients undergoing total knee replacement. Explants were placed in 24-well plates with complete media and allowed to settle for 48 hours. Explants from the same donor were subjected to all treatments: 1) no stimulation (normal media); 2) stimulation with pro-inflammatory signals (LPS and/or IFN-γ); 3) Stimulation + Dexamethasone (Dexa;1µM) or 4) Stimulation + βLap at variable concentrations (1µM-10µM). After 48 hours, media supernatant was collected and explants were cut, half was used to measure GAGs content while the other half were formalin fixed for histological analysis. Media supernatant was used to assess the secretion of PGE2, IL-13, IL-1ra, IL-6, IL-8, MMP-13, MMP-9 and TNF-α.

RESULTS & DISCUSSION: The addition of βLap was able to significantly decrease the secretion of pro-inflammatory cytokines as PGE2 (Figure 1) in a similar way as Dexa control reaching levels close to non-stimulated explants. Furthermore, the addition of βLap was able to decrease the loss of GAGs on the cartilage ECM when compared to stimulated non-treated explants.

CONCLUSIONS: Results pointed out the promising activity of βLap against OA progression. This data corroborates the previously described anti-inflammatory activity of βLap. Further in vivo assessments will be performed to ensure adequate performance of βLap formulations.

INTRODUCTION: An unmet clinical need of being able to glue small bone fractures with a biocompatible, resorbable adhesive system is frequently stated [1]. Bone adhesives have to meet several requirements for all day clinical use. Dental materials and primers influence the design of a surgically realizable bone glue. The major problem in measuring the adhesion properties of a putative bone adhesive primer is to distinguish between cohesive and adhesive forces. Our contribution directly investigates adhesion processes at molecular level via single molecule force spectroscopy (SMFS).

METHODS: A procedure to graft different adhesion motifs onto the tip of an AFM cantilever was established similar to Wildling et al. [2] In SMFS experiments, the AFM tip works as a force sensor with pN resolution. AFM chips were amino functionalized to attach a flexible PEG based linker system. Thereafter, different adhesion motifs were clicked on these spacer and pull-off forces were measured on hydroxyapatite (HAP) mimicking bone and on a TiO₂ coated silicon wafer used as implant surrogate. A specific amino acid sequence (AAS) with phosphorylated serines was chosen as adhesion motif based on its suggested binding properties to HAP in statherin [3].

RESULTS & DISCUSSION: In order to validate tip functionalization and the experimental SMFS procedure per se, the pull-off adhesion values of unfunctionalized, amino functionalized and linker functionalized AFM tips were compared to the phosphorylated AAS sequence and the unphosphorylated sequence on HAP and TiO₂. The mean adhesion values of the phosphorylated AAS were significantly higher. It was proven that phosphonic acid primers play a decisive role in adhering on HAP and TiO₂.

CONCLUSIONS: By the establishment of a procedure to functionalize an AFM tip with adhesion motifs, it is possible to measure adhesion forces at molecular level on different substrates. The phosphorylated AAS can indeed be considered as a fully biocompatible adhesion motif for a bone glue. This is a substantial progress for designing bioadhesive systems.

INTRODUCTION: Additive manufacturing (AM) provide the possibility for the generation of scaffolds with unprecedented structural and functional designs. Particularly, scaffolds made of bioresorbable biomaterial show tremendous potential as a temporary tissue expander to support bone defect regeneration. On the contrary to the conventional scaffolds design concept, i.e. raster-angle, this study established a workflow for the generation of scaffolds with triply periodic minimal surface (TPMS) architecture, finite element (FE) analysis for scaffolds’ Young’s moduli and manufacturing of scaffolds by mean of melt-extrusion based 3D printer. Furthermore, the migration ability of cells in relation to the scaffolds’ geometry was evaluated.

METHODS: Scaffolds with TPMS architecture, i.e., Diamond, Gyroid, and Schwarz P, were generated using customized MATLAB script. FE simulation was performed for the scaffolds’ Young’s modulus and validated experimentally. Melt-extrusion based 3D printer were used for the fabrication of scaffolds with polycaprolactone (PCL). Scaffolds were scanned with micro-computed tomography (µCT) for porosity characterization. After sterilization, scaffolds were seeded with human adipose-derived mesenchymal stromal cells (AdMSCs). Cells migration through the scaffold length was evaluated.

RESULTS & DISCUSSION: This study showed that the understanding of the design-to-manufacturing interface and the limitations of the 3D printer of choice is particularly important to transform digital design concept into reality. In addition, it was showed that although computer-aided generated models can be used as a input for numerical simulation of scaffolds’ mechanical properties, the reliability could be impeded by the anomaly that are present in scaffolds due to the 3D printing processes. More notably, this study illustrated that the scaffolds’ geometry has an influence on cell migration. Specifically, it was showed that scaffolds with a tighter curvature can better promote AdMSCs migration along the scaffolds’ length.

CONCLUSIONS: The advances in AM workflow provide limitless possibilities for scaffold designs with non-non-validated functional properties. Hence, effort should drive to systematic characterization of cell behaviors in relation to scaffolds’ geometries. In the future, such knowledge will be essential for the adoption of shape optimization procedures for the design of scaffolds intended for TERM with predictable functional properties.
The influence of cyclic tensile strain and collagen structure on the alignment and proliferation of multiple vascular cell types

INTRODUCTION: In-stent restenosis is characterized by excessive cell proliferation, which may be driven by the proliferation of vascular smooth muscle cells (VSMC) [1] and multipotent vascular stem cells (MVSC) [2]. In vitro, VSMC reorient perpendicular to uniaxial strain [3], however, in vivo VSMC align parallel to dominant strain direction. In order to explore the role of strain and collagen structure in directing vascular cell alignment and subsequent proliferation, rat aortic VSMC (RASMC) and rat MVSC were first exposed to uniaxial cyclic tensile strain alone. Then, the response of rat MVSC was determined while seeded on decellularized arteries aligned parallel or perpendicular to the direction of strain.

METHODS: RASMC and rat MVSC were cultured on PDMS and strained at 0-10%, 1Hz, uniaxial strain for 24 or 72 hr. Rat MVSC were seeded on decellularized arteries and strained at 0-10%, 1Hz, uniaxial strain parallel or perpendicular to collagen fiber direction for 10 days. Cell number and alignment, and the percentage of Ki67 positive nuclei was determined.

RESULTS & DISCUSSION: On cells seeded on PDMS, both rat MVSC and RASMC aligned perpendicular to strain within 24hr, with rat MVSC showing greater alignment at 24hr and less at 72hr. Strained cells showed decreased cell number by 72hr but not at 24hr. The rat MVSC on decellularized vessels maintained alignment parallel to the fiber direction. Rat MVSC strained parallel to the fiber direction showed increased proliferation when compared to unstrained cells, but cells strained perpendicular to the fiber direction did not.

CONCLUSIONS: These are the first experiments to study the response of MVSC to uniaxial cyclic tensile strain and collagen structure. Both rat MVSC and RASMC exhibit strain-avoidant behavior. Rat MVSC show a higher degree of alignment at the shorter time point, possibly indicating that these cells are critical in early strain response. These experiments have also demonstrated that underlying ECM alignment is critical to rat MVSC response to strain. This suggests that any intervention that influences collagen fiber direction will change how the cells sense the strain.

INTRODUCTION: Substitution of critical bone defects due to injuries, osteoporosis or oncological diseases is an important problem for biomedical research [1]. The evolved promising “regenerative approach” emphasizes the creation of suitable conditions for gradual substitution of the biomaterial with a new-formed bone tissue [2]. In our work, we studied novel 3D printed calcium phosphate-based implants capable for stem cells seeding or saturation with anticancer drugs.

METHODS: Stereolithography 3D printing was used to create bioceramic implants based on non-stoichiometric β-TCP/HA biphase ceramic powder with granulometry 0.3-1 μm. Implants were printed according Kelvin 3D model modified by topological optimization. The biocompatibility and osteoconductive properties of implants were assessed in vitro using human adipose-derived mesenchymal stem cells, and in vivo in a rat tibia defect model. In addition, 3D constructs were saturated with doxorubicin and cisplatin admixed to coating gel consisted of UV-polymerized PEG diacrylate. Drug release kinetic was studied using simulating body fluid (SBF) model.

RESULTS & DISCUSSION: 3D printed constructs possessed an interconnected system of macropores (500-1000 μm in diameter), necessary for the penetration of blood vessels and nutrients inside and through the implants. The saturation of the outer PEG-DA layers with the anticancer drugs resulted in their gradual release for at least 5 days. The constructs demonstrated favourable cytocompatibility and provided suitable 3D conditions for adipose-derived MSCs seeding — after 7 days of cultivation over 80% of the surface was uniformly covered with cells according to MTT staining. In the model of the tibia defect, an intensive formation of new bone tissue at the border of the implant material and uniform colonization of the pores with bone marrow cells were shown. The gradual bioresorption of implanted 3D printed constructs exceeded the corresponded rate for calcium phosphate cement commonly used in the clinic practice.

CONCLUSIONS: Collectively, these data illustrate the possibility to create the osteoconductive calcium phosphate implants capable for bone tissue engineering and local drug delivery by means of additive manufacturing technologies.

ACKNOWLEDGEMENTS: The reported study was funded by RFBR according to the research project № 18-29-11070.

INTRODUCTION: Physiological temperature-setting, printable calcium phosphate (PCaP)-based material offers several possibilities for bone tissue engineering via both osteoconductive and osteoinductive mechanisms [1], depending on the biochemical composition and its pore network architecture. In this study, the in vivo long term performance of novel PCaP scaffolds with different internal porosities on bone regeneration was performed in large animal (equine) model.

METHODS: A PCaP paste was developed by combining α-tricalcium phosphate, nanohydroxyapatite and biodegradable crosslinkable poloxamer [2]. Two types of porous cylindrical architecture (Ø = 9.8 mm, H = 9.5 mm) were fabricated by using a pneumatic extrusion-based printer. Gradient porous scaffolds were produced with four vertically consecutive step-downs in strand-to-strand size (750, 650, 550, and 450 µm, respectively) while scaffolds with constant porosity were produced with a strand-to-strand distance of 750 µm. All scaffolds were printed with a 0-0-90-90° laydown pattern, to ensure constant lateral pore size (500 µm) and with two non-macroporous layer on top. Scaffolds with either a biomimetic gradient or a constant pore distribution were implanted after being encased in a polycaprolactone (PCL, inner Ø = 10 mm, outer Ø = 10.47 mm, H = 10 mm) chamber to prevent infiltration of cells from the periosteum allow bone ingrowth from single direction. Bone defects were created at tuber coxae of the ilium in eight horses (one defect per side). Each horse received both architectures (scaffold type/defect side pairs were selected randomly). The open side of PCL chamber was contacted with native bone. After 7 months of implantation, the animals were euthanized and tissues harvested for µ-CT quantification and histological analysis.

RESULTS & DISCUSSION: The defect site was divided into three main zones having equal volumes. The amount of new bone ingrowth in the constant porosity (109.80 ± 54.50 mm³) scaffold group was significantly higher than gradient scaffold (31.49 ± 11.02 mm³) group, particularly in the bottom and middle of scaffold. Similarly, the estimated percentage of ceramic degradation in the constant porosity group (59.26 ± 13.52%) was significantly higher compared to gradient group (38.38 ± 11.07%).

CONCLUSIONS: The macro-pore pattern of scaffolds, produced from the same composite material, exhibits the essential influences on volume and advance of new bone ingrowth, as well as on material degradation rates.

INTRODUCTION: Clinical gold standards to repair damaged articular cartilage (AC) can result in chondrocyte hypertrophy with poor long-term outcomes [1]. The use of tissue-specific proteins to produce biomimetic extracellular matrix (ECM) scaffolds represents a promising strategy for regenerating phenotypically stable AC [2]. The objective of this study is to probe the matrisome of AC for key proteins that regulate the chondrocyte phenotype, and to stimulate engineered cartilage with recombinant versions of such factors in an attempt to engineer more phenotypically stable AC.

METHODS: AC and calcified growth plate cartilage (GP) from porcine knees were processed for: i) mass spectrometry (MSMS) and Matrisome and String database (DB) analysis or ii) production of pepsin-solubilised ECM. Freeze-drying was used to fabricate AC ECM scaffolds (Φ5×h3mm). Scaffolds, seeded with bone marrow cells were cultured in vitro 4-5 weeks in chondrogenic media (CM) ± Grem1. Biochemical, histological and PCR analysis were performed to determine tissue quality.

RESULTS & DISCUSSION: DB analysis demonstrated that GP and AC contained a distinct array of proteins (>800). Grem1, a known BMP antagonist [3], was identified as a AC-specific factor. Scaffolds supplemented with CM+Grem1 showed comparable levels of chondrogenesis but lower calcification (Alizarin Red staining), lower type I collagen deposition and lower COL10A1 mRNA expression than as scaffolds with CM only.

CONCLUSIONS: In conclusion, this study demonstrated Grem1 to have an anti-hypertrophic effect for cartilage engineered within AC ECM scaffolds. We are currently exploring the in vivo phenotypic stability of such in vitro engineered cartilage.

INTRODUCTION: Naringin is a citrus-derived flavanone currently emerging as a promising anti-osteoporotic and osteogenic phytotherapeutic [1]. However, its bioactivity and ultimately its biomedical applications are hindered by poor in vivo bioavailability as well as lacking optimal cell internalization [1]. Nanocarrier delivery systems are well-recognized to improve entrapped therapeutics’ solubility and increase their cellular uptake. In this sense, the delivery of Naringin to undifferentiated mesenchymal stem cells was explored for the first time to potentiate its biological activity over free drug [2].

METHODS: Naringin-loaded micelles were obtained by self-assembly of synthesized mPEG-PLA copolymer via nanoprecipitation. Micelle biocompatibility and cellular uptake were confirmed by metabolic activity assays and fluorescence microscopy/flow cytometry. Then, the osteogenic activity of the bioinstructive system was studied in adipose-derived mesenchymal stem cells (ASCs) through ALP, Alizarin Red S and osteopontin immunocytochemistry.

RESULTS & DISCUSSION: The amphiphilic mPEG-PLA copolymer self-assembled in water into monodisperse nanomicelles (85 ± 2 nm) with high Naringin encapsulation efficiency (87 ± 5 %). AlamarBlue metabolic activity assays confirmed the highly biocompatible nature of the Naringin-loaded nanomicelles. Fluorescence microscopy and flow cytometry showed efficient cellular uptake in ASCs. Naringin delivery improved ALP activity in earlier timepoints, accordingly 3 and 7 days. Key osteogenic markers such as osteopontin immunocytochemistry and calcium node deposition were highly augmented in the bioinstructive micelle groups. ALP activity analysis with different dose regimen also highlighted the superior osteogenic potential of Naringin-loaded micelles over free drug.

CONCLUSIONS: The biocompatible micelles internalized efficiently in ASCs and elicited an augmented osteogenic differentiation over free drug administration.

INTRODUCTION: The quantitative assessment of vessel architecture and functional perfusion capacity in biomaterials for regenerative medicine approaches requires high-tech analytical methods. Besides ultrasound, optoacoustic imaging or two-photon microscopy, magnetic resonance imaging (MRI) and microcomputed tomography (MicroCT) are prime examples to achieve a precise, reliable and robust readout. The chicken embryo model with its chorioallantoic membrane (CAM) offers an assay for evaluation of vascularization of tissue-engineered constructs with short experimental times with high grade outcome.

METHODS: In vivo perfusion capacity with MRI and ex vivo angio-architecture by MicroCT was assessed in the same scaffold. The readouts were supported by comprehensive histological analysis comprising blood vessel density and characteristics. Two different potential biomaterials, for bone regeneration, a synthetic and a natural one, were evaluated. Natural porcine collagen-based Optimaix™ (Matricel) has a laminar structure, which mimics aligned entities found in the diaphysis. Synthetic DegraPol® (Ab medica SpA), on the other hand, was chosen as its highly porous structure resembles spongy bone.

RESULTS & DISCUSSION: The newly developed pump-assisted perfusion technology for the CAM model allows for a more even, reliable and efficient distribution of contrast agent in the vessel system compared to the conventional manual injection. Perfusion capacity (MRI) and total vessel volume (MicroCT) strongly correlated for both biomaterials. In addition, a detailed analysis of branches, junctions, vessel length and radius confirmed the different vessel architectures in the two biomaterials. It was found that the highly porous DegraPol® exhibited significantly higher numbers of branches (3.5-fold), number of junctions (5-fold), total branch length (2.3-fold), however, lower number of branches per junction (0.65-fold), mean branch length (0.87-fold), and lower mean radius (0.76-fold) when compared to Optimaix™.

CONCLUSIONS: Here, we demonstrate for the first time the functional and structural analysis of the vascularization in biomaterials after one week of incubation on the CAM. Based on these results, we conclude that the two imaging methods, MRI and MicroCT, allow for a comprehensive analysis of the vascularization pattern and efficiency of biomaterials in a cost-effective, well-established and easy-to-handle immune-incompetent preclinical model.

INTRODUCTION: Integration of injectable hydrogels on biological surfaces is a key feature in minimally invasive tissue engineering approaches. However, insufficient mechanical and adhesive properties at high level of water content and the need for tissue treatment limit the clinical translation of injectable hydrogels for load-bearing tissues such as articular cartilage. Moreover, using commercial tissue adhesives such as fibrin glue and COSEAL for implantation of pre-formed scaffolds result in weak adhesion to tissues [1-4]. To address these limitations in cartilage tissue engineering, we developed a highly adhesive and injectable hydrogel with enhanced mechanical performance, which can be formed in situ without any cytotoxicity.

METHODS: The developed nanofibrillated cellulose (NFC) reinforced double-network hydrogel was synthesized by mixing PEGDMA, calcium sulphate, NFC, and Irgacure 2959 in distilled water. The mixture was homogenized at 12000 rpm and sodium alginate was added. The PEGDMA molecules were crosslinked by ultraviolet irradiation. Tissue samples were prepared from bovine articular cartilage.

RESULTS & DISCUSSION: By implementing various toughening mechanisms in our designed biomaterial, interface integration is maintained and the crack propagation is controlled under loading. This composite double-network hydrogel significantly increases the adhesive and cohesive fracture resistance while containing ~90% water in its structure. The proposed dissipative hydrogel exhibits adhesive properties which are superior to clinically used glues. In particular, the attachment of the developed hydrogel presents ~10 times higher adhesion strength to articular cartilage than that of the currently available tissue adhesives such as Tisseel. The Cytocompatibility, enhanced mechanical properties, swelling, and injectability of the developed hydrogel were also demonstrated.

CONCLUSIONS: Considering the remarkable features of the hydrogel, our approach can facilitate development of minimally invasive adhesives for clinical translation.

INTRODUCTION: Designing a bioink often requires a compromise between formulations that support high shape fidelity bioprinting (e.g. appropriate ink viscosity & yield stress) and those that are optimal for supporting cell migration, growth, and differentiation [1]. Fibrin is a natural biopolymer commonly used as biomaterial for tissue engineering and is in widespread clinical use (typically at high concentrations, 60–120 mg/ml). Fibrin can also be made printable through the use of a gelatin-based carrier gel, and has been used to bioprint multiple tissues [2]. The goal of this study was to explore how fibrin concentration regulates chondrogenesis of human bone marrow MSCs (hMSCs) within fibrin based bioinks, and to reinforce these bioinks with networks of 3D printed PCL for their future use in endochondral bone tissue engineering.

METHODS: Two bioinks composed of gelatin, hyaluronic acid, glycerol and two different concentrations of fibrinogen (3.5 & 5 mg/ml) [2], and containing hMSCs (5x10^6 cells/ml), were 3D-printed inside PCL structures and crosslinked at 20 °C in a thrombin bath (20IU/mL in DMEM) for 30 minutes. Constructs were then cultured in chondrogenic media (containing TGF-β3) supplemented with 10µl/ml Aprotinin, for 3 weeks at 5% pO2 followed by 2 weeks at 20% pO2. Biochemical assays (DNA, sGAG and Hydroxyproline) were performed at day 0, 21 and 35. Alcian Blue, PicroSirius Red and Alizarin Red staining were also undertaken.

RESULTS & DISCUSSION: For both fibrin concentrations, sGAG and collagen deposition increased with time in culture, with significantly higher levels of collagen deposition observed in the 3.5% group at day 35. This was also observed histologically, with homogenous staining for sGAG and collagen observed after 35 days of culture.

CONCLUSIONS: Taken together, these data demonstrate that both fibrin bioinks support robust chondrogenesis, with the softer 3.5% fibrin supporting higher levels of collagen deposition. We have already shown with other materials [3] that in vivo degradation is a key parameter for better healing. We expect that the lower material density bioink will degrade faster in vivo, allowing better infiltration and integration with host tissue. Future studies will explore the potential of these fiber reinforced cartilage templates for the regeneration of large bone defects by recapitulating the developmental process of endochondral ossification.

INTRODUCTION: In the cranio-maxillofacial area, bone allografts are extensively used for skeletal regeneration in several forms (blocks, powders…). To improve their use in irregular or hardly accessible sites [1], we have developed an allogenic bone paste injectable in a cohesive form, made of partially demineralized and heated bone powder. The purpose of this work is to investigate the in vivo bone regenerative capacity of this bone paste and its in vitro ability to stimulate mesenchymal stromal cells (MSC) osteogenic properties as well as polarize macrophages towards anti-inflammatory phenotype.

METHODS: In vivo: Critical size defects were performed on syngeneic Lewis1A rat calvaria (2x5mm per rat, n=6/condition). Defects were filled with bone powder (0.5-1mm), bone paste or left unfilled (control). After 7 weeks, the mineral volume (MV)/total volume (TV) ratio was measured by micro-CT and bone tissues was histologically analysed. In vitro osteogenic properties: human MSC from bone marrow (hBM-MSC) were grown in proliferative or osteogenic medium and changed every other day for 21 days. Afterwards, the alkaline phosphatase (ALP) mRNA expression and enzymatic activity were quantified. In vitro macrophage polarization: human monocytes isolated from circulating blood were cultured in presence of 20ng/mL of GM-CSF (inflammatory environment) or its vehicle, in contact with powder or paste for 3 days. Their resulting phenotypes were evaluated thanks to the mRNA expression of a panel of pro-inflammatory (IL-12, IL-6, TNF-α) and pro-regenerative factors (IL-10, TGF-β, VEGF).

RESULTS & DISCUSSION: After 7 weeks of implantation, histological and micro-CT analyses revealed the formation of new bone tissue in the filled defects. MV/TV was significantly higher in the defects filled with bone paste as compared to those filled with bone powder (p<0.01) or left empty (p<0.001). RT-qPCR analyses indicated that ALP mRNA expression in hBM-MSC cultured on bone paste was significantly higher that of cells cultured on bone powder (p<0.01). ALP enzymatic activity was similarly found to be higher in hBM-MSC cultured in contact with the bone paste (p<0.01). Interestingly, macrophages in contact with bone paste showed increased pro-regenerative factors mRNA expression (IL-10 and VEGF) in comparison with bone powder.

CONCLUSIONS: Our data demonstrated the substantial in vivo bone regenerative capacity of the bone paste. We also demonstrated that bone paste is able to support the in vitro osteogenic differentiation of hBM-MSC and contribute to favors the switch of inflammatory macrophages to pro-regenerative ones. Taken together, these data highlight the potential of this innovative bone paste as an injectable allogeneic bone substitute.

INTRODUCTION: Reconstruction and repair of cartilage is difficult due to its inability to self-healing and regeneration. Until today a variety of replacement matrices and scaffolds with suitable microenvironment is abandoned. However, this study concentrates on developing acellular xenogenic cartilage matrices as an alternative in biomedical and clinical applications.

METHODS: The full thickness ear cartilage derived from caprine was decellularized post slaughter with Triton X-100 and hypertonic-hypotonic solution [1, 2]. The effect of decellularizing agents on cells and extracellular matrix (ECM) was analyzed by H&E staining, DNA content, scanning electron microscopy (SEM), proteoglycan, collagen, elastic fiber staining and biochemical quantization, nanoindentation study (mechanical property), swelling behavior and in vitro hemocompatibility study. The developed materials were further characterized for in vivo biocompatibility (rabbit) subcutaneously and later on analyzed by gross observation, histology and biochemical study. Ultimately, acellular cartilages were implanted in osteochondral defects in rabbit for 3 months followed by histology and micro-CT study.

RESULTS & DISCUSSION: Complete cellular loss was ascertained by H&E staining and DNA (p≤0.5). However proteoglycan was significantly reduced (p≤0.5). Additionally, the acellular materials were confirmed to be non-reactive and non-hemolytic biomaterials as assessed by in vitro hemocompatibility study. The in vivo experiment revealed that the developed acellular cartilages are biocompatible. Upon implantation in rabbit osteochondral defects, the gross observation, histological and micro-CT studies depicted that these acellular matrices significantly boosted the regeneration of cartilage along with the subchondral bone tissue.

CONCLUSIONS: Therefore, the successful outcome opens a new approach to design cost effective acellular xenogenic cartilage biomatrices with versatile physical characterizations that can be applied to numerous areas of tissue engineering.

INTRODUCTION: The development of 3D scaffold systems for regenerative medicine is limited due to the lack of oxygen and nutrients in macrostructures. One of the promising approaches to stimulate cell metabolism, proliferative activity and viability via mitochondrial activation is low-intensity LED irradiation (LILI). Nevertheless, the mechanism of these LILI effects may vary among different cell types. This work aims to reveal LILI effects on viability and metabolic activity of human mesenchymal stem cells (MSC), human neuroblastoma (Sk-N-BE(2)), and mouse embryonic fibroblasts (3T3) immobilized within 3D hydrogels.

METHODS: Three cell types were used – primary MSC culture derived from the bone marrow, neuroblastoma cell line Sk-N-BE(2), fibroblast cell line 3T3. They were cultured in full growth medium (DMEM/F12 supplemented with 10% FBS (HyClone, USA)). For 3D culture, cells were stained with Hoechst 33258 (Sigma, USA) and MitoTracker Green FM (ThermoFisher, USA) and encapsulated in the PEGylated fibrin hydrogel [1, 2] at a concentration of 1×10^4 cell per 200 ml of gel, the resulting gel thickness was 1.5 or 3 mm. Continuous non-thermal LILI was performed using two LED types: 1) 633nm, 1200s, 22kJ/m^2 and 2) 840nm, 600s, 21kJ/m^2. Cultures were monitored via time-lapse microscopy using CellInsight CX7 (ThermoFisher, USA). Live/Dead, MTT, and Alamar blue assays were used to study cell viability. PicoGreen assay were applied to reveal the amount of cells. Morphology in 3D cell culture was studied via scanning electron microscopy.

RESULTS & DISCUSSION: Cells encapsulated with the gel had the reduced proliferative activity. For instance, after 24 hours of cultivation, the proliferation of MSC was 35% (in 1.5 mm gels) or 60% (in 3 mm gels) less than that in 2D cultures. When irradiated during encapsulation, MSC proliferated only 15% and 25% less than those in 1.5 mm and 3 mm gels, respectively. The use of LILI during hydrogel polymerization increased cell viability by 10% for all cell cultures. Moreover, the irradiation of cells immobilized within the hydrogel resulted in the increase in mitochondrial activity (15%).

CONCLUSIONS: We showed that LILI of cells suffering from oxygen and nutrient starvation in 3D culture increased both their viability and metabolic activity. The developed approach to improve cellular activity in 3D scaffolds can be widely applied in tissue engineering.

ACKNOWLEDGEMENTS: The study was supported by the Russian Science Foundation (grant № 15-15-00132, hydrogel formation) and the Russian Foundation for Basic Research (№ 17-02-01248, cell viability assays; № 17-02-00832, LED irradiation).

INTRODUCTION: Organ failure leads to decreased quality of life and morbidity. Current gold standards for organ transplantation have inherent weaknesses like donor site morbidity, donor shortage, and immuno-compatibility. A tissue engineering approach by using biomaterials fabricated from natural polymers and seeded with autologous stem cells has potential to restore functional organs as they are bio- and immuno-compatible, and stem cells have the capacity for self-renewal and differentiation into specific linages. However, to fabricate these functional tissue equivalents there is limited understanding about interaction between stem cells with natural polymers present in the extracellular matrix (ECM) like collagen, fibrin and elastin¹,²,³. Therefore, the aim of our study was to investigate how different 3D environments made of proteins found in the natural ECM affect cellular behavior of human adipose derived stem cells (hADSCs) as a preliminary step to design 3D constructs for tissue and organ regeneration.

METHODS: Scaffolds from natural polymers (collagen, fibrin and elastin) were fabricated by custom designed processes and their material properties thoroughly characterised. Scaffolds were seeded with hADSCs and implanted in 9 SD rats. In vitro cell studies were carried out where survival, proliferation, and phenotype were investigated. In vivo, output was carried out by haematology, µCT and immuno-histology.

RESULTS & DISCUSSION: Collagen and fibrin scaffolds had fourfold higher swelling ratio than elastin, but elastin was the most stable polymer in culture conditions of all scaffolds. Differentiation results in scaffolds indicated significantly higher (P <0.05) adipogenic phenotype (PPARg and CEBP) than osteo, chondro-genic phenotypes by day 28. In vivo results showed a higher vascular network on collagen and fibrin scaffolds than the elastin scaffold.

CONCLUSIONS: Collagen had higher cell adhesion and proliferation in vitro and integration properties in vivo whereas fibrin had less cell adhesion in vitro but higher vascularization in vivo. Cells on elastin maintained its undifferentiated state in vitro but in vivo elastin was an structurally unstable scaffold. These findings about how polymers present in the natural ECM affect hADSCs behaviour in vitro and in vivo can help designing 3D constructs for tissue and organ regeneration.

INTRODUCTION: Vascular tree formation and their network organization has previously been shown to be sensitive to the mechanical environment in vitro, yet the specific relationship between the mechanical factors such as geometry, shape, pressure, flow characteristics and vascular organization in vivo is not well understood. The present study aimed to investigate the effect of yolk shape on vascular network organization, within developing chicken embryos cultured in containers with different geometries, resulting in a different mechanical environment of the egg yolk. Using both laser speckle contrast (LSCI) and laser doppler perfusion imaging (LDPI) techniques, the spatio-temporal changes of heart rate and flow velocity in the vascular networks within developing chicken embryos were determined.

METHODS: PDMS based artificial egg shell systems: 3D geometric (cube, cylinder and triangular prism shaped) containers based on oxygen permeable thin polydimethylsiloxane (PDMS) membranes were assembled using soft lithographic templates. 3D printed poly(lactic acid) frames were used as mechanical support. Fertilized white leghorn chicken eggs were incubated with 38°C and 65% humidity under regular rotation. After 3-days of incubation, chicken embryos were transferred to the artificial geometric culture systems as shown in the figure.

RESULTS & DISCUSSION: Results showed that the heart beat rate (figure -right) and vascular network density were influenced by changing the local mechanical environment of egg yolk. Further, LSCI revealed changes in the perfusion rates within the chick vasculature. Changes in vascular organization with respect to differences in the local microenvironment of the yolk were observed.

CONCLUSIONS: With the ultimate goal to understand in vivo vascular organization, fluid flow and growth factor gradient patterns adjacent to the developing chicken blood vessels will next be introduced in the PDMS systems. This 3D integrated platform offers the possibility to evaluate the effect of multiple signals towards vascular organization in a single system.

INTRODUCTION: Three-dimensional microenvironment is a need to study the event cascades of liver fibrosis in vitro [1]. In this study, we fabricate a series of three-dimensional (3D) electrospun scaffolds by wet electrospinning process modified with different ratios of collagen-I to fibronectin to achieve optimized distribution of these two ECM (Extracellular matrix) proteins on the fiber surface to create an in vitro liver disease model by using LX-2 cells.

METHODS: 3D electrospun PLGA (poly(lactic-co-glycolic)acid) fibrous scaffolds were modified with rat-tail Collagen-I and plasma fibronectin (Life Technologies, Carlsbad, California, USA) at five different ratios by using chemisorption process (C:F_1:0; C:F_0:1; C:F_1:1; C:F_3:1; CFF_9:1). We have cultured LX-2 cells, a human hepatic stellate cell line on 3D electrospun scaffolds for 14 days. Matrigel culture was used as a negative control for activated hepatic stellate cells whereas TCP (tissue culture plate) culture used as a positive control to the activated phenotype.

RESULTS & DISCUSSION: A ratio of 3:1 of collagen-I to fibronectin was found to be optimum for surface modification of electrospin poly(lactic-co-glycolic acid) (PLGA) fibers by chemisorption process. In 3:1 collagen-I to fibronectin modified scaffolds the total protein content increased by ~2 fold compared to collagen-I modified and ~1.5 fold compared to 1:1/9:1 collagen-I to fibronectin modified scaffolds. We have cultured LX-2 cells on this scaffold over 14 days and found that LX-2 cells acquire more quiescent phenotype throughout the culture period and shown significantly (p<0.001) lower expression of alpha smooth muscle actin and collagen-I.

ACKNOWLEDGEMENTS: Financial support was received NTU-Northwestern Institute for Nanomedicine (Nanyang Technological University, Block N3.1, #01-03, 50 Nanyang Drive, Singapore 637553).

INTRODUCTION: Composites have been introduced for clinical application for their ability to blend the mechanical and chemical properties of multiple materials. In this study medical grade Poly(L-lactic) acid (PLLA) was reinforced with short Ca-doped phosphate-based glass fibres to assess the influence in human mesenchymal stromal cells differentiation due to Ca deposition.

METHODS: The materials were initially mixed by melting PLLA granules with the short fibres, before being extruded to form a homogenous filament, which was pelletized and used as feedstock for compression moulding. Mechanical properties and degradation profile were studied along 8 weeks. Human mesenchymal stromal cells were cultured on the surfaces of scaffolds, and the metabolic activity, alkaline phosphatase production and mineralisation monitored over a three week period.

RESULTS & DISCUSSION: As made the composite materials had a bending strength of 51MPa±5, and over the course of eight weeks in PBS the average strength of the composite material was in the range 20-50 MPa. The short fibre reinforcement made no significant difference to cell proliferation or differentiation, but had a clear and immediate osteoinductive effect, promoting mineralisation by cells at the material surface.

CONCLUSIONS: It is concluded that the PLLA/PGF composite material offers a material with both the mechanical and biological properties for potential application to bone implants and fixation, particularly where an osteoinductive effect would be valuable.

Figure 1: From right to left: SEM image of compression moulded samples; Confocal image of cell morphology and attachment. Blue staining for nucleus (DAPI), red for cell body (Phalloidin) and green the actin filaments representing adherence (Vinculin); Alizarin red staining of cell-seeded PLLA and PLLA/PGF discs.
Engineered bridge proteins with dual affinities for bone morphogenetic protein (BMP)-2 and collagen improve controlled release of BMP-2 for bone regeneration

P.S. Briuez¹, A. Abu-Khalil¹, J.A. Hubbell¹
Presenting Author: Priscilla S Briuez, pbriquez@uchicago.edu
¹Institute for Molecular Engineering, University of Chicago, Chicago, USA

INTRODUCTION: BMP-2 is a potent growth factor (GF) to promote bone regeneration. Particularly, it is currently used in the clinic for spine fusion, under the product InFuse® Bone Graft, by Medtronic. However, the clinical safety of BMP-2 has been questioned, due to serious side effects in treated patients, such as ectopic bone formation or nerve injuries. These side effects can be partially imputed to the supra-physiological dose used as well as to the lack of appropriate delivery system [1]. Here, we engineered bridge proteins with strong affinities for both BMP-2 and collagen matrix to control the release of BMP-2, for application in bone regeneration.

METHODS: Bridge proteins were designed as chemical conjugation or recombinant fusion of an anti-collagen I Fab with a GF-binding domain, displaying strong affinity for BMP-2. Release tests of BMP-2 from collagen gels (PureCol, Adv. BioMatrix) were performed by incorporating 500 ng/mL of BMP-2 into collagen gels, with or without bridge proteins (10:1 molar ratio). Release buffer was taken and refreshed every day for 6 days, and the amount of released BMP-2 was quantified by ELISA.

RESULTS & DISCUSSION: Bridge proteins were produced and purified to high quality, as assessed by SDS-PAGE and western blot analysis. Affinities of the bridge proteins to collagen I was confirmed by ELISA-based binding assays, and dissociation constants K_D were determined to be at 1-3 nM, which is considered as high-affinity. Similar methods were used to demonstrate binding of BMP-2 to the bridge proteins, with affinities in range of 50 nM. Further release assays showed that bridge proteins allow strong retention of BMP-2 into collagen matrices, with about 20% released after 6 days, in contrast to BMP-2 alone (i.e. without bridge proteins) that is fastly released at about 70% after 1 day and 80% at 6 days. Increased retention was additionally visualized by immunohistochemistry of retained BMP-2 into the collagen matrices. In vivo efficacy studies on bone regeneration are ongoing in the critical-size calvarial defect model in mice.

CONCLUSIONS: In this study, we engineered bridge proteins able to increase the retention of BMP-2 into collagen matrix. Increased local delivery of BMP-2 is expected to increase local efficacy and lower side effects in vivo. Should this be confirmed in our case, our proposed delivery system is particularly interesting in terms of clinical translation as it does not require modification of BMP-2 or of the collagen, both being approved in the clinic.

INTRODUCTION: Pancreatic ductal adenocarcinoma (PDAC) has an extremely low survival rate [1], with its resistance to most current treatment methods being one of biggest therapeutic challenges. Traditional 2D systems for therapeutic analysis is unable to mimic the in vivo tumour niche and it has been shown that 3D systems respond to drugs differently than 2D systems. Several groups have developed spheroid systems with different cell types, to study the effect of radio and chemotherapy for PDAC treatment [1]. However, spheroid systems have several disadvantages including lack of long term maintenance, difficulty in structural tuning. To tide over these, we have previously developed and novel scaffold based PDAC tumour model [2]. In this work we present for the first time, we study the effect of radio and chemotherapy on our novel 3D PDAC model.

METHODS: PANC-1 cells were cultured in our novel scaffolds for 46 days, which is the longest in vitro reported culturing period. Based on our previous work, on day 29 cells in the scaffolds have formed a physiologically relevant phenotype. Therefore, on day 39, we applied chemotherapy gemcitabine (GEM) at concentrations of 10, 50 and 100µm, radiotherapy (dose range of 2-8 Gy) and a combinatory treatment (10µm GEM & 6 Gy). The tumour inactivation kinetics were monitored and quantified up to 17 days post-treatment with live/dead staining and in situ quantification of caspase-3/7 apoptotic marker with confocal laser scanning microscopy (CLSM).

RESULTS & DISCUSSION: Our findings show that the cell viability in the 3D scaffolds remained high up to 17 days post treatment and then significantly decreased. The inactivation kinetics were dose and treatment dependent with the combined chemo-radiotherapy treatment inducing higher cell death. The caspase-3/7 activation followed a similar pattern for all the treatment conditions. Similar post treatment induced apoptosis trends in a dose dependent manner have been previously reported for PDAC xenografts.

CONCLUSIONS: We present here for the first time, chemo and radiotherapy screening on our novel scaffold based PDAC in vitro model. We highlight the positive effect of combinatorial treatment and the effect of dosage for both chemotherapy and radiotherapy. Our microscopic observations of dose dependent changes in apoptotic marker and cell viability match with previously published data of PDAC xenografts, highlighting the feasibility of using this model to accurately study PDAC and its treatments in vitro, taking us closer to an animal free research.

INTRODUCTION: Myocardial infarction (MI) results in the necrosis of cardiomyocytes often leading towards heart failure (HF). Although cellular therapies aim to replace these cells, their efficacy remains challenging [1]. Cardiac tissue engineering (CTE) utilising human pluripotent stem cell-derived cardiomyocytes (hPSC-CMs) may offer a solution however the relative immaturity of these cells is a concern [2]. In this study, we aimed to generate reproducible, anisotropic scaffolds with structural cues capable of maturing hPSC-CMs in-vitro and delivering these to the infarcted heart in addition to human pluripotent stem cell-derived endothelial cells (hPSC-ECs) to develop a primitive vasculature that could aid retention of delivered cells.

METHODS: Medium-chain-length polyhydroxyalkanoates (MCL-PHAs), a family of bioresorbable polymers with mechanical properties conducive to CTE were generated via bacterial fermentation. These polymers were electrospun to generate reproducible scaffolds. hPSC-CMs generated via a small molecule differentiation protocol were seeded onto PHA scaffolds for 1 week. Gene expression and optical mapping studies revealed hPSC-CMs remained functional on the PHA scaffolds. Morphological assessment conducted after 1 week showed organised α-actinin alignment as compared to hPSC-CMs cultured on fibronectin (P≤0.01). Additionally, hPSC-CMs cultured on PHA scaffolds were shown to be highly anisotropic as compared to hPSC-CMs cultured on fibronectin. Scanning electron microscopy was completed to identify topographical cues that may be responsible for this alignment.

RESULTS & DISCUSSION: hPSC-ECs were generated via a growth factor protocol and were seeded onto PHA scaffolds without prior preconditioning resulting in a functional monolayer with angiogenic properties comparable to collagen culture. Viable co-culture conditions conducive to hPSC-EC proliferation and tube formation were identified and used to co-culture hPSC-ECs and hPSC-CMs on the PHA scaffolds. Finally, initial in-vivo studies show myocardial compatibility of the PHA scaffold itself with subsequent studies set out to investigate the functional benefits of the complete cell-seeded cardiac patch.

CONCLUSIONS: Here we have developed a new delivery system capable of aligning and maturing hPSC-CMs whilst maintaining hESC-EC function thus this scaffold has the potential to promote angiogenesis and facilitate retention of the delivered cells.

INTRODUCTION: Though it is well known that bone is the preferential homing site for breast cancer metastasis, the disease remains largely incurable with only palliative treatment options. This clinical void can be partially attributed to the lack of suitable animal models that mimic key features of metastasis of human tumor cells to the human bone microenvironment. To address this, we designed a humanized tissue engineered bone model. This model holds tremendous promise for further investigation into the factors involved in osteotropic metastasis of breast and other cancers.

METHODS: Polyethylene glycol (PEG) hydrogels (PEG was selected as a defined non-inductive 3D environment) [1] were seeded with various combinations of human mesenchymal stem cells (hMSCs) from diverse sources and bone morphogenetic protein-2 (BMP-2). These constructs were subcutaneously implanted in mice. After bone formation, human breast cancer cells (MDA-MB-231) were subsequently introduced to the system and their dissemination to the humanized ossicles could be tracked via bioluminescent imaging. Cancerous lesions in the bones were monitored via both microCT and histological evaluation.

RESULTS & DISCUSSION: As a first step, the parameters were optimized for maturation of the humanized bone marrow constructs. PEG hydrogels were seeded with various combinations of human mesenchymal stromal cells (hMSCs) from diverse sources and bone morphogenetic protein-2 (BMP-2). We first determined the minimum concentration of BMP-2 and minimum cell density for bone marrow-derived hMSCs from healthy donors. Strikingly, we found that 20 million hMSCs/ml without presence of BMP-2 could remodel PEG gels into ossicles, as shown by microCT analysis and histology. Moreover, these implants not only still contained hMSCs, but were also highly infiltrated by murine osteogenic, endothelial and hematopoietic cells as demonstrated by FACS analysis. Importantly, tissue type and donor health significantly affect hMSC potential. Cancer cells added at different times of bone development disseminate to the ossicles within 2 weeks, and reduced bone formation by increasing osteoclasts activity.

CONCLUSIONS: Taken altogether, this intricate xenograft model featuring humanized bone microenvironments and human tumor cells has potential to be a powerful tool for studying osteotropic metastasis. It can be utilized to study the molecular cargo that may be involved in homing cancer cells to bone, priming the pre-metastatic site for secondary lesions, and mapping out morphological changes in the bone microenvironment that contribute to disease progression. Furthermore, it may prove valuable as preclinical tool for screening novel therapeutics that combat metastatic processes allowing for earlier intervention and vastly improved patient outcomes.

INTRODUCTION: Muscular dystrophies (MDs) are inherited disorders that manifest as progressive muscle wasting and weakness [1]. Cripto protein has been recently found to have therapeutic value in alleviating muscle myopathies by regulating muscle regeneration and satellite cell progression through myogenesis [2]. In this study, we establish a highly reliable methodology for producing large quantities of the Cripto protein and further clarify the strategy in which we can encapsulate the Cripto into the microgel carrier for the purpose of controlled release. PEG-fibrinogen (PF) hydrogels provide the substrate for protein production. For the purpose of controlled release in situ delivery vehicle, both well-established PF and preliminary but promising Pluronic®F127 fibrinogen (FF127) hydrogels are attractive and potentially applicable.

METHODS: In order to attain efficient production of Cripto, PF hydrogel-based microcarriers were designed to enable mammalian cell survival and proliferation, as well as the secretion of large amounts of therapeutic proteins. Cripto-overexpressing HEK 293T cell lines were encapsulated in the PF microcarriers and cultivated in stirred suspension bioreactors. PF microcarriers were prepared to possess high mechanical strength in order to resist the shear forces and biodegradation associated with being immersed in a long-term suspension culture in the bioreactors. Subsequently, two distinct injectable controlled-release systems were designed for the encapsulation of the Cripto: PF hydrogel-based pre-formed microspheres, and in situ formed FF127 hydrogel-based implants.

RESULTS & DISCUSSION: The yield of Cripto proteins produced using this system was significantly higher than the traditional two-dimensional (2D) system. This result was in accordance with previous production cycles of other proteins performed in our laboratory. Likewise, both injectable systems exhibited similar sustained-release profiles of Cripto for up to 27 days, though with a prominent difference in encapsulation rate in favor of FF127. The Cripto that was released was biologically active and promoted the proliferation of mouse myoblasts. We further demonstrated that the release rate of Cripto from PF-hydrogel microspheres could be controlled by tuning the crosslinking density of the hydrogel, which was controlled by varying the concentration of poly(ethylene glycol) diacrylate (PEG-DA).

CONCLUSIONS: Concurrent with the optimization of both delivery systems in vitro, it is intended that the significance of these results be further investigated by means of follow-up in vivo trials.

Designing a novel bioengineered substrate as a treatment for AMD
R. McCormick¹, I. Pearce², A. Haneef¹
Mccormick, Rachel, R.Mccormick@liverpool.ac.uk
¹Eye and vision department, Institute of Ageing and Chronic Disease, University of Liverpool, William Duncan Building, 6 West Derby Street, Liverpool L7 8TX ²Royal Liverpool University Hospital, St Paul’s Eye Unit, Prescot Street, Liverpool, United Kingdom

INTRODUCTION: Age related macular degeneration (AMD) is the third most prevalent cause of blindness worldwide, and the leading cause of blindness in industrialised countries. In AMD, the Bruch’s membrane, a section of the retina, thickens with age, resulting in impaired waste/nutrient exchange between the retinal pigment epithelial (RPE) cells and the choroid. This in turn leads to the photoreceptor death and eventually permanent central vision loss. There are two types of AMD, wet and dry. Dry AMD, also known as geographic atrophy, is the most common affecting 90% of AMD patients and there is currently no effective treatment. Considering there is no current treatment for atrophic AMD and with its prevalence anticipated to rise due to increasing life span, a treatment for this debilitating condition is essential. Here we have optimised the production of a bioengineered substrate to act as an artificial Bruch’s membrane, suitable for growing RPE cells as well as a bioactive layer that will deliver active molecules at a controlled rate to break down the diseased native Bruch’s membrane.

METHODS: 25% w/v PET (polyethylene terephthalate) dissolved in hexafluoro-2 propanol (HFIP) scaffolds, capable of growing RPE cells in their native role, were produced through electrospinning. RPE cells were plated on 2cm² scaffolds at a density of 50,000 cells. Electrospun PET was also subjected to tensile testing. For nanoparticle production PGLA (polyglycolic-lactic acid, 10% HFIP) and polyglycolic (PGA, 10% acetone) were subjected to different working distances and voltages to ensure the formation of nanoparticles, using SEM images as a confirmation. Following on from this they were then tested for their ability to encapsulate, protect and release substrates.

RESULTS & DISCUSSION: Our results have shown that electrospinning, 25% PET can produce nanoscale fibres and confirm that electrospun PET is a suitable scaffold for RPE cells. Tensile testing of PET fibres show electrospun PET has a high elasticity, compared with cast PET sheets which are extremely brittle. We have also shown that electrospraying of biodegradable compounds (PGA, PLGA) is able to form reproducible nanoparticles that are capable of encapsulating biological moieties. Degradation studies using FITC (fluorescein isothiocyanate) tagged bovine serum albumin (BSA) and enzymes have shown that these nanoparticles are capable of releasing BSA and enzymes (lipases, collagenases), at a controlled rate. Gel enzyme assays show the nanoparticles do not affect the function of the enzymes and are likely to protect the enzymes from degradation.

CONCLUSIONS: This work shows that PET is a suitable scaffold for RPE cells and that electrosprayed biodegradable nanoparticles are able to encapsulate, protect and sustain the release of biological enzymes. Future work will focus on the optimisation of the specific cocktail and release of enzymes suitable for the breakdown of drusens for apical side of replacement RPE and Bruch’s membrane, as a treatment for dry AMD.

INTRODUCTION: In clinics, Bone Morphogenetic Protein 2 (BMP2) was applied for the support during spinal fusion. Further BMP2 was tested in IVD models and showed potential for IVD regeneration. The aim of this study is the investigation of BMP2 and the BMP2 analogue, L51P, on different cell types of the human IVD in 3D alginate beads, particularly their plasticity to undergo bone formation.

METHODS: Human nucleus pulposus (NPC), annulus fibrosus (AFC) and cartilaginous endplate cells (CEPC) were each encapsulated in 1.2% alginate at a density of 4 Mio/mL. NPC, AFC, and CEPC beads were then cultured in α-MEM or osteogenic medium (OM) supplemented with 10% FBS and 100 ng/mL BMP2 and/or L51P for 21 days. Medium supplemented with cytokines was refreshed twice per week. Beads were snap frozen with liquid nitrogen after 7 days for mRNA analysis of Aggrecan (ACAN), Collagen type1 (COL1), Collagen type 2 (COL2) and runt-related transcription factor 2 (RUNX2) qPCR. Further, beads were stained with Alcian Blue after 21 days.

RESULTS & DISCUSSION: ACAN expression was the highest up-regulated in IVD cells stimulated with OM and 100 ng/mL BMP2 and L51P compared to negative control (basal medium only) in NPC, AFC and CEPC (mean ± SEM NP: 18.95 ± 15.65). The same was true for COL2 expression (NP: 72.47 ± 62.95). COL1 remained unaffected (N=2).

CONCLUSIONS: In this study we showed the trend of an increase in ACAN and COL2 gene expression in stimulated cells. Interestingly the co-treatment of BMP2 and L51P showed a cumulative effect towards an increased ECM production.

Biochemical gradients to form a 3-D osteochondral in vitro model
1 3B’s Research Group – Biomaterials, Biodegradable and Biomimetics, Headquarters of the European Institute of Excellence on tissue Engineering and Regenerative Medicine, AvePark, 4805-17 Barco, Guimarães, Portugal 2 ICVS/3B’s- PT Government Associate Laboratory, University of Minho, Guimarães-Braga, Portugal 3 The Discoveries Centre for Regenerative and Precision Medicine, Headquarters at University of Minho, Avepark, 4805-017 Guimarães, Portugal 4 Bio-Acoustic MEMS in Medicine Laboratory, Canary Center at Stanford for Cancer Early Detection, Stanford School of Medicine, Palo Alto, California 94304, USA 5 Electrical Engineering Department by courtesy, Stanford University, Stanford, California 94305, USA

INTRODUCTION: Gradients of 3-D complex functional patterns at micro-scale are common in nature [1]. While diverse fabrication techniques based on material science, micro-scale engineering, and microfluidics have been used to synthesize biomimetic and tailored microenvironments [2,3], a great need is still present for improved methods of gradient tissue engineering. Here, we developed the precise spatial control over both cell/tissue phenotype and pre-vasculature formation, which opens-up possibilities for the study of complex tissues interfaces, with broader applications in drug testing and regenerative medicine.

METHODS: The fabrication of microparticles gradient was performed combining methacrylated gelatin (GelMA), gellan gum (GG), and the hydroxyapatite microparticles (HAp). The temperature was controlled to mix the interface of two polymeric layers, being the second added at 10ºC higher than the first one. The promoted convection was used to drive the microparticles forming the gradient. After crosslinking, the freezing step was tuned using an external cover of styrofoam forcing the ice crystals to grow linearly. A bioreactor device was designed to culture fat pad adipose-derived stem cells and microvascular endothelial cells in 3-D biochemical gradients.

RESULTS & DISCUSSION: Using control over temperature and crosslinking, hydrogel-like structures were built in 3-D isotropic and anisotropic HAp gradients. Finally, an in vitro osteochondral tissue model was obtained. Results showed a significant difference (p < 0.05) of SOX9 and bone markers from top to bottom regions of the 3-D gradient structures under dynamic conditions using a custom dual-chamber bioreactor.

CONCLUSIONS: In the present work, microparticle and biochemical gradients were combined into iso- and anisotropic architectures. Overall, these results enable the precise control of 3-D gradients anisotropy with broad applications in interfaced tissue engineering and drug testing with special focus on regenerative medicine.

ACKNOWLEDGEMENTS: The authors are grateful for the FLAD and FCT funding (SFRH/BD/92565/2013).

INTRODUCTION: Bioprinting, thanks to the unique flexibility and spatial accuracy it offers, has a promising future for the deposition of cells and extracellular matrices toward the fabrication of physiologically relevant 3D tissue models. Most bioprinting platforms offer switching single-nozzle printheads. In contrast, industrial inkjet printheads feature hundreds of nozzle in parallel while enabling the deposition of drops in physiologically relevant resolution. We hypothesize that this high-throughput industrial technology will enable the cost-effective fabrication of 3D tissue models, potentially leading to the industrialization of bioprinting. To test our hypothesis, we are investigating the reliability of the printing process, its throughput and its impact on cells.

METHODS: A 3D Bioprinting platform was developed and set up with a special Xaar 128 printhead compatible with water-based inks. Bioinks based on culture media with viscosity modifiers were prepared and characterized to improve the stability of the cell suspensions while remaining liquid enough for inkjet printing (<15mPa*s). 3T3 mouse fibroblast, A549 human alveolar basal epithelial and HUVEC were cultivated and suspended in bioinks (3x10^6 cells/mL = 100% concentration) and their sedimentation rate measured. 7mL of the cell-loaded bioinks were fed into the ink system and were kept there for up to 35min of alternating sequences of purging, printing and settling at room temperature. Batches of cell-loaded bioinks were printed as one big drop in a petri dish that was subsequently divided into n=3 wells for culture. To quantify the stability of the process, cell concentration was measured after each batch printing. To measure the impact of the process on the cells, a viability test (Trypan Blue exclusion assays) was performed.

RESULTS & DISCUSSION: When using DMEM with 10%FBS as a bioink, suspended cell concentration in the printed batches dropped to 31% after 5min settling and sedimented cells were observed to clog the nozzles. Increasing the viscosity of the bioink by adding 5% Ficoll PM400 led to an increase of the cell concentration to 81% after 5 minutes settling while limiting the clogging of the nozzles. This indicates that the rheological properties of the bioink can be tuned to improve the stability of the printing process. Viability directly after printing and for up to 4 days culture remained over 85%, suggesting that the printing process and the addition of Ficoll has a limited impact on the cells.

CONCLUSIONS: Our study demonstrates that high-throughput and reliable cell deposition can be achieved through industrial inkjet by modifying the rheological properties of the bioink.
The use of skeletal muscle-derived pericytes in tissue engineering of skeletal muscle graft based on 3D pluronic-fibrinogen (FF-127) hydrogel environment

R. Hamami¹, D. Seliktar¹

Presenting Author: Raziel Hamami, Razielh@campus.technion.ac.il

¹Department of Biomedical Engineering, Technion Israel Institute of Technology, Haifa 3200003, Israel

INTRODUCTION: Muscular dystrophies (MDs) are genetic disorders characterized by progressive muscle wasting, leading to limitations in motor capacity and in many cases to progressive paralysis and death. In this present study, we aim to rejuvenate skeletal muscle function by developing an injectable approach for intra-arterially delivery of cells to the injury site using biomaterials combined with cell therapy.

METHODS: For physically cross-linked cell-seeded microcapsules, a cell suspension 3×10⁶ cells/mL polymer mixture was dripped through a droplet-based microfluidic device into a warm (37 °C) gelation bath containing continually stirred media, forming micro-carriers with a diameter ranging from 150 to 500 μm.

RESULTS & DISCUSSION: In the first experiments, FF-127 micro-carriers were seeded with skeletal muscle-derived pericytes (MP) using a new droplet-based microfluidic device, as the basis of our skeletal muscle repair strategy. Guided by the fact that cell viability directly correlates to the success of cell transplantation therapies, viability of encapsulated cells were investigated 1, 4, 7, 14 and 21 days after culture. Viability, morphology, proliferation and cell recovery yields were shown to be higher than photo-chemically cross-linked over physical crosslinking micro-carriers made from a similar material, especially in the MPs. Moreover, throughout syringe needle flow, cells experience three types of mechanical forces that can lead to cell disruption: (i) a pressure drop across the cell, (ii) shearing forces due to linear shear flow, and (iii) stretching forces due to extensional flow. In this study, our proposed system is cell-compatible as harsh mechanical or crosslinking processes such as UV and aggressive chemical crosslinking mechanisms are avoided.

CONCLUSIONS: Our studies demonstrate a novel strategy for injectable FF-127 cell-seeded micro-carriers production using an effective microfluidic device. These micro-carriers successfully preserved the viability and concentration of human MPs required for positive transplantation later on. Using fewer cells to achieve a similar number of transplanted, viable cells would greatly reduce the cost, time, and effort required to restore lost skeletal muscle function using transplantation protocols.

INTRODUCTION: Layer-by-Layer (LbL) is a technique that permits the formation of nanostructured surface coatings useful for delivery of bioactive drugs and proteins, like growth factors (GF). Bone morphogenetic protein-2 (BMP-2) promotes osteogenic differentiation of mesenchymal and other cells and is used in the treatment of non-healing bone fractures. However, bolus injections of BMP-2 are rapidly cleared-off and lose their activity rapidly. Hence, high dosages are needed, which can result in inflammation, increased cancer incidence and further complications, in addition to high costs of treatment. Thus, the need for controlled release systems lowering therapeutic concentrations of GF are badly needed.

METHODS: Heparin, chondroitin sulfate and their oxidized forms as polyanions were combined with chitosan and collagen I as polycations to form various multilayer coatings on model materials with getting advantage of the intrinsic cross-linking formed between oxidized glycosaminoglycans (GAGs) and polycations to improve multilayer stability and affect the release of BMP-2. The myoblast cell line C2C12, which can differentiate into osteoblasts was seeded on 5 µg/mL BMP-2 loaded multilayers. Cell viability was investigated by Qblue assay; adhesion using immunohistochemical staining, osteogenic differentiation by alkaline phosphatase (ALP) assay and alizarin red-S staining. In addition, studies on release of BMP-2 were done by ELISA.

RESULTS & DISCUSSION: C2C12 cells cultured directly on the top of multilayers showed that particularly BMP-2 loaded multilayers made of oxidized GAGs promoted an osteogenic differentiation that was nearly comparable to the positive control, when 5 µg/mL BMP-2 was added directly to the medium. Interestingly, the BMP-2 had synergistic effect on cell adhesion and spreading. BMP-2 in oxidized chondroitin sulfate multilayers was successfully loaded to the layers, sustainably released over time and affected cell differentiation more than the soluble BMP-2.

CONCLUSIONS: The results show that oxidized GAGs forming intrinsically cross-linked multilayers are useful as reservoirs for sustained release of BMP-2 in which the intrinsic cross-linking affected BMP-2 release, improved multilayers stability due to the resulting stiff surface compared to the native ones, supported cell adhesion, proliferation and subsequent differentiation. This can pave the way for coating implants and scaffolds for repair and regeneration of bone fractures.

INTRODUCTION: Osteoarthritis (OA) results from a combination of genetic and environmental factors which cause imbalance between anabolism and catabolism and affect articular cartilage. To tackle the problem, inhibition of pro-inflammatory cytokines which are excessively expressed in OA joint is necessary. After screening of 40 Traditional Chinese Medicine (TCM) compounds, the bioactive ingredients with most potent effect for treatment of OA were further evaluated.

METHODS: The anabolic effects of 40 TCM compounds in a 3D pellet culture model, were assessed biochemically (GAG/DNA) using human OA chondrocytes. The most chondrogenically active compounds were tested in an inflammatory model consisting of 3 days of inflammatory induction with cytokines (IL-1β/TNF-α) with and without supplementation of TCM compounds. The anti-inflammatory effects of the compounds were assessed transcriptionally (q-PCR and RNA sequencing), biochemically and histologically.

RESULTS & DISCUSSION: From the 40 compounds tested, several showed significant anabolic effects. After induction of inflammation, the pro-inflammatory and catabolic marker genes were up-regulated, and GAG/DNA ratio was significantly decreased; while several compounds had anti-catabolic effects, by down-regulating pro-inflammatory markers including MMPs and COX-2. After 2 weeks of treatment with the compounds following inflammation, the GAG/DNA ratio was restored by Psoralidin, (Ps), Vanilic acid (VA), Protocatechuicaldehyde (PCA), Epimedin C (Epi C), 4-Hydroxybenzoic acid (4-HBA) treatment. Immunohistochemistry and Safranin-O staining confirmed the accumulation of cartilaginous matrix in compound treated pellets.

CONCLUSIONS: Of the 40 TCM compounds tested, Ps, PCA, VA, 4-HBA and Epi C, showed promising anabolic and anti-inflammatory effects. A local drug delivery system for the bioactive compound is envisioned and their efficacy for cartilage repair will be tested.

Microencapsulated human induced pluripotent stem cells (hiPSC) for the cell and molecular therapy of type 1 diabetes mellitus (T1D): Preliminary in vitro and in vivo data

G. Basta, P. Montanucci, T. Pescara, R. Calafiore
Presenting Author: Riccardo Calafiore, riccardo.calafiore@unipg.it
Laboratory for Cell Transplants and Biohybrid Organs, University of Perugia, Perugia, Italy

INTRODUCTION: Replacement of destroyed pancreatic islet beta-cells with functionally competent insulin-secreting cells, may represent the final cure for T1D. hiPSC committed to differentiation into beta-like cells could provide for virtually unlimited source of insulin producing cells. We then aimed at evaluating differentiation pathways of hiPSC towards beta-like cell phenotypes, able to secrete insulin in vitro, and in vivo, in experimental animal models of T1D, upon microencapsulation in human recombinant elastin monomers (ELR).

METHODS: hiPSC underwent in vitro differentiation protocols. We carefully characterized the obtained cell hiPSC spheroids, in terms of morphology, viability and cell phenotyping, by molecular biology, electron microscopy and immunofluorescence technical procedures. Spheroids underwent triple ELR coating. Coated spheroids were analyzed in terms of both, in vitro and in vivo retention of viability and function. In vitro, the spheroids were exposed to glucose at different concentrations to determine insulin secretion and content. In vivo, the coated spheroids survival was evaluated upon intraperitoneal graft into immunoincompetent NOD/scid (n=4) mice and immunocompetent CD-1 mice (n=4). Cell/tissue reaction to graft was examined upon peritoneal lavage and flow cytometry analysis of spleen and lymph nodes cell phenotypes. Graft of ELR-coated (vs. uncoated) spheroids was performed in either normal or Alloxan-induced diabetic mice.

RESULTS & DISCUSSION: At term of in vitro differentiation, hiPSC spheroids showed good viability, as assessed by staining with ethidium bromide and fluorescence diacetate, and fair insulin content, upon staining with diphenyl-thiocarbazone. Expression of hormones typical of pancreatic islet cells (insulin, glucagon, somatostatin) was qualitatively comparable to that of differentiated islets. ELR coating of the spheroids, upon transmission electron microscopy examination, was clearly detectable and it did not alter viability of the encapsulated sub-cellular organelles and hormone granules of the hiPSC spheroids. In vitro metabolic data showed insulin secretory patterns and content, consistent with the presence of differentiated beta-like cells. At two weeks of graft, peritoneal lavage in NOD/scid mice was associated with 90% viability retention of the retrieved coated vs. control uncoated spheroids. At the same post-transplant time period, and using the same procedure, CD-1 mice showed viability that was higher for the coated vs. control uncoated spheroids. Peritoneal cellular response to graft was incomparably lower for coated vs. uncoated hiPSC spheroids. Two diabetic mice grafted with ELR-coated hiPSC spheroids showed partial decline of blood glucose, as compared to controls, but only in fasting conditions. New transplant experiments are in progress.

CONCLUSIONS: These very preliminary data seems to support the possibility that hiPSC may serve for beta-like cell surrogates, for beta-cell substitution therapy in T1D. ELR coatings are associated with tangible immunoprotection properties. Implementation of hiPSC maturation pathways may likely improve the metabolic outcome in the next series of experimental transplant studies.

INTRODUCTION: Electrically conductive biomaterials are of great interest for the engineering of excitable tissues, and as electrodes for implant devices. Metals, such as gold or platinum, are highly conductive and chemically inert, but are expensive and mechanically incompatible with tissue. As alternative, conductive polymers have been explored, however, these are difficult to process after synthesis and lose their conductivity after repeated cycles of electrical stimulation [1]. In this study the possibility of developing a conductive, biocompatible, inexpensive and easy-to-make substrate for excitable tissue engineering (with the main focus being on cardiac applications) was examined through compositing polyurethane or polycaprolactone with graphene.

METHODS: Four types (normal, large flake, high surface area and hydrophilic) of commercially available graphene were composited and solvent cast with polycaprolactone and medical grade polyurethane. Graphene weight percentages between 10% and 66% were tested. The formed composites were assessed for electrical conductivity, wettability, surface topology (SEM), and mechanical properties (nano-indentation). Biocompatibility was tested using C2C12 mouse myoblast cells, RN22 rat Schwann cells, and primary human cardiac myocytes through the PicoGreen assay and fluorescent microscopy with Vybrant DiD live cell staining. An inexpensive and autoclavable bioreactor system for the effective delivery of electrical stimulation to cells through the graphene composites was designed and custom built. The level and distribution of electrical field strength and current density within the bioreactor chamber was determined through FEM computer simulation. Monophasic pulsed electrical stimulation was delivered to human primary and human iPSC derived cardiac myocytes cultured upon the composites, either in monolayer or in a 3D collagen gel. The effect of electrical stimulation on cell growth, morphology and distribution and cardiac gene expression profile was determined.

RESULTS & DISCUSSION: Computer simulations showed that 1.7 S/m is the critical conductivity for the substrates. All four graphene-polymer types were able to achieve greater conductivities, the highest value being 64 S/m. Conductivity was not decreased by 6 days of continuous electrical stimulation Addition of hydrophilic graphene decreased contact angle to approx. 60°, while all other types increased it. Material roughness, porosity, reduced modulus and hardness were also increased by the addition of graphene. C2C12 and RN22 cells adhered and proliferated on hydrophilic composites to an equivalent or greater extent than on pure polymer substrates. Hydrophilic composites also performed well with cardiac myocytes in bioreactor experiments.

CONCLUSIONS: This study demonstrates that graphene-polymer composites offer a valuable alternative to conductive polymers in engineering of cardiac tissues.

INTRODUCTION: Olfactory ensheathing cells (OECs) demonstrate convincing efficacy in animal models of spinal cord injury and they can be safely harvested from human patients to facilitate autologous transplant. However, only 1% of OECs remain viable at the lesion site and the spinal cord microenvironment lacks the structural guidance cues required for effective regeneration. Such factors limit the current effectiveness of OEC transplant and provide opportunities for significant improvement. We aimed to optimize gel formulation and cell alignment to generate cellular OEC hydrogels suitable for spinal cord repair.

METHODS: OECs were extracted from Sprague-Dawley rats and cultured for 14 days. Cells were then seeded into various collagen and fibrin hydrogels. Gels were incubated for 16 hours in vitro, after which time live-dead assay or immunocytochemistry were performed. OEC-seeded gels were tested in vivo using a rat dorsal resection model of spinal cord injury. Forepaw posturing was quantified and post-mortem histology performed. The effect of OEC alignment was assessed using dorsal root ganglia neurons.

RESULTS & DISCUSSION: The survival of OECs differed between the various collagen and fibrin hydrogel formulations tested (p<0.001 one-way ANOVA, n = 17). 10% v/v fibrin conferred the best cell survival with 85% of OECs remaining alive. Collagen hydrogels promoted the highest proportion of p75NTR immunopositive cells (78%, p<0.0001 one-way ANOVA, n = 24). Compared with OEC collagen hydrogels, fibrin OEC hydrogels resulted in significant improvements in rat forepaw posturing at 14 days post-injury (p<0.05, independent t-test, n = 5). Highly-aligned OEC constructs guided the linear extension of dorsal root ganglia neurites.

CONCLUSIONS: Collagen and fibrin hydrogels promote favorable OEC survival and increase the proportion of cells expressing a key repair marker. Collagen hydrogels can also be used to create highly-aligned OEC constructs, which guide neurites and may help ensure organized axon regeneration across the spinal cord lesion site in the future. This work marks important progress to improve the survival, phenotype and organization of OECs for spinal cord repair.

Figure 1: Confocal micrograph of engineered cellular tissue containing highly-aligned OECs capable of guiding neurite regeneration.

The development of a novel 3D bioprinted smart responsive dressing to treat skin scars
Presenting Author: Rita Ibanez, ritaibanez@rcsi.com
1Tissue Engineering Research Group, Royal College of Surgeons in Ireland, Ireland 2Trinity Centre for Bioengineering, Trinity College Dublin (TCD), Ireland 3Advanced Materials and Bioengineering Research (AMBER) Centre, RCSI & TCD, Ireland 43B’s Research Group – Biomaterials, Biodegradables and Biomimetics, University of Minho, Avepark 4805-017 Barco, Guimarães, Portugal 5ICVS/3B’s – PT Government Associate Laboratory, Braga/Guimarães, Portugal

INTRODUCTION: Current treatments for skin injuries are limited by the prevalence of bacterial infection. Herein we propose a bi-layered antimicrobial scaffold-based dressing that mimics the epidermal and dermal layers of skin, potentially enhancing wound healing while limiting bacterial infection. The aim of the study was to use 3D printing technology to print a gelatin-methacrylate (GelMA) porous scaffold representative of the dermal layer combined with a collagen-chitosan film with antimicrobial potential to represent the epidermal surface.

METHODS: 3D GelMA constructs with varying inter-filament distances (0.6 mm – 2 mm) were printed with a Biobots 2 (Allevi, USA) 3D printer. Construct biocompatibility was determined culturing primary human fibroblasts on the scaffolds and analysing with Picogreen and live-dead staining. Collagen, chitosan and Collagen:Chitosan (Col:\Chit) 1:1 v/v films were prepared. Mechanical tensile testing of the films was performed. An antimicrobial assay was conducted using Staphylococcus Aureus (SA). Biocompatibility and proliferation were assessed using a Human keratinocyte cell line (HaCat) and analysed with Alamar blue and Picogreen.

RESULTS & DISCUSSION: High resolution scaffolds were obtained with 3D printed GelMA; different sized pores (272 µm - 898 µm) were achieved by altering inter-filament distance (p<0.05). Col:\Chit films present mechanical characteristics similar to native skin with a significant increase in ultimate tensile strength (UTS) compared with chitosan alone (p<0.05) while no difference was observed on the Young’s moduli (data not shown). The films also show remarkable antimicrobial activity against SA (p<0.05). The film support HaCat viability (data not shown).

CONCLUSIONS: We have shown that it is possible to print a versatile GelMa scaffold targeted towards dermal regeneration and we also produced an epidermal film that is both antibacterial and capable of supporting mammalian cell growth. The development of this new antimicrobial bi-layered scaffold-based dressing may lead to an effective new treatment for burn injuries that may have a significant impact on patients, clinicians and healthcare systems.

Wounds that fail to proceed through the normal phases of wound healing in an orderly and timely manner become chronic wounds. These non-healing wounds represent a challenging and escalating problem which exposes patients to additional complications, decrease in their quality of life and long-term treatment with high costs [1,2]. Herein, we develop a drug-controlled release scaffold as a wound healing treatment. A functionalized scaffold was fabricated as a prophylactic wound healing therapy. The fabrication and functionalisation were then followed by morphological, mechanical, thermal and biochemical characterization of the produced scaffolds, including the release profile of the loaded drugs. A drug loaded scaffold has potential value as a wound healing treatment for abdominal wall surgical wounds.

INTRODUCTION: Approximately 10% of individuals with bone fractures fail to heal under the usual treatments, where the underlying reasons are currently not totally understood \cite{1}. It is well established that mobilization and activation of resident mesenchymal stem/stromal (MSCs) and/or adjacent tissue' cells are involved in triggering of bone healing. This process is strictly controlled by complex interactions with the physical and chemical environment. We here aim to develop a meaningful in vitro model where the response of MSC to individual signals can be studied in a naïve microenvironment resembling naïve skeletal stem cell niche.

METHODS: Human femoral heads were collected after patient’s total hip arthroplasty with informed consent and agreement of the local ethics committee. Bone slices of 3 mm thickness were decellularized and decalcified. Cylindrical-shaped scaffolds with 5 mm diameter were prepared and lyophilized. The efficiency of the decalcification and decellularization protocol was confirmed by x-ray imaging of scaffolds’ bone mineral density and qualitative histology confirmation of nuclei absence, respectively. Information of the decellularized scaffold structure was obtained by micro computed tomography (m-CT). MSCs were isolated from human bone marrow of femoral heads, as previously described, and seeded in passage 2-5 into the scaffolds at different cell densities. Their morphology and distribution through the scaffold was assessed using CellTracker™ Green labelling. MSCs’ metabolic activity was studied throughout culture time using reduction of resazurin based-assays.

RESULTS & DISCUSSION: The here established protocol resulted in homogenous and regular decellularized and decalcified bone scaffolds. The scaffolds size did not present significant inter- or intra-donor variation. The conservation of human native bone ultra-structure was illustrated by histology of decellularized scaffolds and confirmed with m-CT quantitative analysis of connectivity and trabeculae features. Seeding of green labelled MSCs in the scaffolds revealed attachment of cells to porous surfaces after 24h as well as homogeneous distribution in the scaffold volume over time. Viability of MSCs and their sustained metabolic activity was assessed through the reduction of resazurin in culture media over time, showing that viable MSCs persist over long culture times. Increase of metabolic activity over time was slower when compared with 2D monocultures.

CONCLUSIONS: Our results show that meaningful human bone-derived 3D in vitro models could successfully be produced and support MSCs viability. Future studies will further investigate the MSC phenotype in the scaffolds as well as their response to microenvironmental cues.

INTRODUCTION: Restoration of damaged tissues through the activation of endogenous progenitors is an attractive therapeutic option [1]. A deep evaluation of the intrinsic stem/progenitor cell properties as well as the reciprocal interactions with injured environments is of critical importance. In this context, it has been recently shown that a population of circulating progenitors, defined as circulating healing (CH) cells, characterized by a lineage-negative/CD45-negative (Lin-CD45-) profile, possess a strong chemotactic potential, being responsive to the signals released by an injured environment as the one generated by a bone fracture [2]. These stimuli directed their migration, with subsequent engraftment and differentiation into specific cells belonging to the affected tissue [2].

METHODS: A distinctive core signature characterizes CH cells. In particular, genes encoding for cell surface antigens were deeply analyzed and Bone Marrow Stromal Cell Antigen 2 (BST2) was identified as an efficient CH cell marker. Taking advantage of a mouse model of stabilized transverse femoral fracture we demonstrated the bone marrow (BM) origin of BST2+ CH cells, their homing capacity toward the lesion site as well as their specific activation under injury conditions.

RESULTS & DISCUSSION: We here report for the first time the existence of a rare population of BM-derived progenitors co-expressing LepR and BST2, traceable in the circulation of naive mice in response to normal physiological stimuli, and more importantly, activated under injury conditions. CH cells share the distinctive property of many adult progenitors to be retained in a quiescent, non-cycling state, until they are needed for maintaining tissue homeostasis or enhancing tissue repair. In our experimental model, during the acute phase response of the host to bone fracture, BM-derived CH cells start to proliferate and over-express specific genes related to motility pathways, leading, in the later phases of the healing process, to an efficient cell engraftment within the hard callus and the articular cartilage of injured mice. The proof that injury induces the release of high levels of HGFA in the serum and that CH cells significantly over-express the gene encoding for the HGF-receptor (Met) when they circulate in physiologic conditions or when they are present in the bone marrow of injured mice has suggested that HGFA could be also involved in their priming. Indeed, the administration of a single dose of rHGFA mimicked the fracture effects, prompting the transitioning of CH cells to an alerted state and the functional changes implicated in the complex events underlying cell migration and activation.

CONCLUSIONS: Taken together, these results could pave the way for the identification of new strategies to enhance and potentiate endogenous regenerative mechanisms for future therapies.

INTRODUCTION: Drug discovery is a long and expensive process, whose efficiency is often limited due to the poor predictivity of in vitro models currently exploited in the pre-clinical phases [1]. Among others, cardiac toxicity represents a prevalent adverse effect preventing the drug to reach the market. Here we present a new beating heart-on-chip platform able to generate functional 3D human cardiac microtissues, whose electrophysiological signals can be directly extracted during culture by means of an integrated electrical measurement system. The proposed microfluidic platform represents a powerful pre-clinical cardiac model to screen the cardiotoxic effects of new compounds.

METHODS: The platform design builds upon our previous beating-heart-on-chip [2]. 3D cell laden hydrogels are conditioned through a combination of biochemical and mechanical (uniaxial strain 10-12% at 1Hz) stimulations. Microtissue electrophysiological measurements are recorded by means of an integrated electrical system consisting of paired electrodes inserted in specific positions through dedicated guide microchannels. Neonatal rat cardiomyocytes (NRCMs) or human induced pluripotent stem cell derived cardiomyocytes (h-iPSC-CMs) were embedded at 100·10⁶ cells/ml in fibrin gel (20mg/ml) and cultured within the platform for up to 10 days. Microtissue electrical activity, named field potential, was recorded after the onset of a spontaneous and synchronous beating of the whole cardiac construct (between day 6 and day 10). The effects of compounds known to alter the cardiac electrical activity (Verapamil, Terfenadine, Sotalol) were evaluated by evaluating the variations in the field potential morphology induced after 10 min of administration at incremental concentrations.

RESULTS & DISCUSSION: Cardiac microtissues from NRCMs and h-iPSC-CM showed spontaneous beating after 3 days of mechanical stimulation within the platform, which was enhanced and synchronized during time (day 6-10). Field potential measurements from rat microtissues revealed that Verapamil prolongs the repolarization time in a dose-dependent manner (i.e. 1-1000nM). Terfenadine resulted to prolong the repolarization time of human cardiac microtissue at high concentrations (i.e. 100-1000 nM) and Sotalol showed to prolong the repolarization wave peak in both rat and human- cardiac microtissues.

CONCLUSIONS: The beating heart-on-chip generates functional cardiac microtissues responding to drugs in a physiological manner [3]. The innovative integrated recording system makes the platform a unique tool for direct on-chip cardiotoxicity drug screening.

INTRODUCTION: Biodegradable polymers, such as polycaprolactone (PCL) and polyhydroxybutyrate (PHB), are of great importance in tissue engineering. Moreover, PHB possesses piezoelectric properties allowing for the delivery of electrical and electrochemical stimuli to cells. Recently, it has been reported that diazonium chemistry can be successfully utilized to improve wettability of polyvinylidenefluoride/polymethylmethacrylat. However, its influence on the piezoelectric response is still not studied in sufficient detail. Therefore, the aim of this study is to improve the wettability and preserve the piezoelectric properties of biodegradable scaffolds based on PCL and PHB using diazonium chemistry for tissue engineering.

METHODS: The fibrous PCL and PHB scaffolds were fabricated via the electrospinning technique. The prepared samples were soaked in 20 mM solutions of 3,4-dicarboxybenzenediazonium tosylate. After immersion, the samples were treated by UV-light using a Sylvania G15T8 15W (254 nm) UV-lamp. A sessile drop method and Wide-range $d_{33}$ meter were used to investigate the wettability and piezoelectric properties of the samples before and after surface modification.

RESULTS AND DISCUSSION: Figure 1 presents the results of the wettability and piezoelectric charge constant $d_{33}$ measurements before and after polymer scaffolds surface modification. It can be seen that water contact angle is significantly decreased for PHB and PCL scaffolds after surface modification (Fig. 1A). Besides that, almost unchanged $d_{33}$ coefficient was observed after treatment of PHB scaffolds (Fig. 1B). The slight deviation can be explained taking into account a thin molecular COOH layer onto the fiber surface. The piezoelectric properties of PHB scaffolds are in good agreement with literature.

CONCLUSIONS: The diazonium chemistry allows to significantly improve surface wettability while maintaining the piezoelectricity of the polymer scaffolds due to the formation of the COOH-functionalized molecular layer. The PCL and PHB scaffolds modified with diazonium salt can be useful for different tissue engineering applications.

**Figure 1:** (A) Wettability and (B) piezoelectric $d_{33}$ charge coefficient of the biodegradable fibrous scaffolds based on PCL and PHB before and after surface modification

INTRODUCTION: The adult neural crest-derived stem cells (NCSCs) have significant potential for regenerative medicine [1]. The promising sources for the isolation of adult NCSCs are the skin dermis (SD) and hair follicle (HF) due to the come-at-able and low invasive biopsy procedure. The main purposes of the study were an isolation, large-scale expansion and comparative characterization of HF- and SD-derived NCSCs.

METHODS: The HF NCSCs were obtained by explant method [2] in our modification [3]. The SD NCSCs were isolated by original method combining enzymatic dissociation, pre-plating and cultivation under selective conditions. The SD and HF NCSCs characterization was provided by flow cytometry, karyotyping, ICC, qPCR and Bio-Plex multiplex assay. Also a frequency of CFUs, ability to self-renewal, spherogenesis and directed multilineage differentiation were determined.

RESULTS & DISCUSSION: Adult SD and HF NCSCs were successfully obtained from a same skin samples. For cell isolation two skin specimens ø4 mm per donor (n = 10) were used. HF and SD NCSCs had slightly different morphology (elongated vs compact polygonal). SD NCSCs showed a higher growth rate than HF NCSCs during expansion under standard 2D (PDT 30.2±3.8 vs 34.4±8.0 h) and 3D fibrin hydrogel (PDT 20.8±0.5 vs 21.8±0.8 h) conditions. SD NCSCs also showed a higher CFUs frequency: 34±3% compared to 25±5%. HF and SD NCSCs have similar phenotype: SOX10+ CD271+ NESTIN+ SOX2+ CD73+ CD90+ CD105+ CD140a+ CD140b+ CD349+ CD34- CD45- CD56 CD117- HLA-DR-. Importantly, after large-scale expansion the population of SD NCSCs contains more SOX10, CD271, CD105, CD140a, CD146 and CD349 positive cells. HF and SD NCSCs expressed at similar level epy following genes: OCT3/4, SOX2, KLF4, C-MYC, NANOG, SOX10, TFAP2A, LNGFR, NESTIN, SNA1L1, SNA1L2, TWIST1, VEGFA, FGFA, NGF, BDNF, GDNF, NTF3, and NTF4/5. Significantly elevated expression of SOX9 was specific for HF NCSCs. On protein level HF NCSCs produced more IL-6, IL-8, IL-16, sIL-2Ra, MCP-1, M-CSF and HGF, while SD NCSCs produced more IL-3, CTACK, SDF-1a, GM-CSF, SCGF, VEGF-A, FGF-2 and NGF. It was shown the ability of adult HF and SD NCSCs to directed differentiation into the neurons, Schwann cells, adipocytes and osteoblasts.

CONCLUSIONS: The HF and SD are useful sources for large-scale expansion of adult NCSCs with similar biological properties. SD NCSC demonstrated higher proliferation rate and formed more homogenous population. SD NCSC isolation method is cheaper, easier and minimal time consuming.

Toward building cartilage by mechanotransduction: Evidence that primary OA chondrocytes can transduce mechanical loads through central metabolism
D. Salinas¹, B. Mumey², R. Carlson³, R. June⁴
Presenting Author: Ron June, rjune@montana.edu
¹Computer Science Department, Westminster College ²Gianforte School of Computing ³Chemical & Biological Engineering ⁴Mechanical & Industrial Engineering and Cell Biology & Neurosciences. Norm Asbjornson College of Engineering, Montana State University, USA

INTRODUCTION: Mechanical stimulation has long been known to affect chondrocyte synthesis of matrix molecules [1]. Matrix molecules are largely composed of non-essential amino acids. Non-essential amino acids are synthesized from central metabolism. The objective of this study is to determine if chondrocytes can transduce mechanical loads through central metabolism in a manner consistent with synthesis of non-essential amino acids.

METHODS: Primary human chondrocytes from Grade IV OA patients were expanded for 1 passage, encapsulated in 4.5% v/v agarose, and stimulated with 5±1.9% sinusoidal compression for 0, 15, or 30 minutes [2]. Metabolites of central metabolism were analyzed using LC-MS, and central energy metabolism was modeled using metabolic flux analysis [3].

RESULTS & DISCUSSION: Compression induced significant changes in the metabolites. These metabolite changes resulted in reaction fluxes for central metabolism for both intervals (0-15 and 15-30 min). These fluxes depended on the donor, but all donors responded to compression.

CONCLUSIONS: The greatest magnitude and variation in metabolic fluxes was encompassed by the reactions modeling the enzymes adenylosuccinate lyase and adenylosuccinate synthetase isozyme 1, aspartate decarboxylase, aspartate oxidase, lactate dehydrogenase, fumarase, and malate dehydrogenase (ASal, ASde, ASox, PYLAC, TCA7, and TCA8). These reactions contribute to producing non-essential amino acids necessary for matrix production. For example, the protein sequence of collagen (COL2A1) includes 62 aspartate residues which are directly produced by TCA7 and TCA8. These data indicate that tissue engineering solutions to cartilage repair may benefit from directed interventions that enhance metabolic production of amino acid precursors by mechanotransduction.

INTRODUCTION: Collagen-glycosaminoglycan (CG) scaffolds [1] are a proven biomimetic regenerative dermal template, which lack growth factors (GFs) that could improve their regenerative potential. Those could be provided by platelet-rich plasma (PRP) [2] - an autologous source of GFs. Therefore, we incorporated PRP into CG scaffolds and evaluated its effects for wound repair.

METHODS: After incorporation of PRP into CG scaffolds, the resulting scaffolds (PCG) were analyzed by histological techniques, mechanical testing (5N load cell), ELISA for GFs release (e.g., PDGF-BB, bFGF and VEGF) and scaffolds an in vitro vascularization assay [2].

RESULTS & DISCUSSION: PRP was homogenously incorporated into CG scaffolds. PCG scaffolds had a tensile modulus 3 times higher than that of the PRP clot alone. GFs were successfully released from PCG for up to 14 days and the novel scaffolds elicited a 2-fold increase in vessel formation over CG scaffolds in vitro.

CONCLUSIONS: Fabrication techniques were developed to homogeneously incorporate PRP in CG scaffolds (PCG). These novel scaffolds had improved mechanical properties, released GFs for up to 14 days and demonstrated enhanced vascularization over control scaffolds in vitro. To fully confirm the effectiveness of PCG for wound repair, in vitro and in vivo dermal and epidermal studies are being performed.

INTRODUCTION: Cellular self-assembly (SA) recapitulates distinct phases of articular cartilage development [1] and can be used to engineer cartilage comparable to the native tissue in vitro [2]. SA has also been used to produce hypertrophic cartilage templates capable of forming a bone ossicle in vivo via endochondral ossification [3]. Leveraging the benefits associated with self-assembled μtissues from MSCs, our goal is to biofabricate an osteochondral implant using such organoids as biological building blocks. The objective of this study was to develop a high-throughput (HT) method for producing cellular μtissues that could be used in 3D bioprinting applications, and use self-organisation to generate hyaline cartilage via fusion of these μtissues.

METHODS: HT-SA: Molten agarose (4 % w/v) was cast into a custom microwell array. Each array consisted of 401 x 1 mm Ø round bottom wells. MSCs and chondrocytes (3:1 ratio) were seeded to create four pellet sizes, doubling in density from 0.1 x 10⁴ to 1.6 x 10⁴ cells/pellet. μtissue growth was evaluated over 7 days, 4 days in expansion medium (+ FGF-2) and 3 in chondrogenic medium (CDM+). Self-Organisation: Primed μpellets were seeded into 3 mm Ø agarose wells (2 % w/v). The self-organised (SO) tissues were evaluated visually, mechanically, biochemically, and histologically over 4 weeks (in CDM+). Bioprinting μTissues: Prior to printing, an alginate hydrogel was pre-crosslinked using 40 mM calcium chloride solution, yielding a printable bioink (2.45 % w/v LVG alginate). The μpellet laden bioink was extruded through a piston assisted pneumatic microextrusion system (3D Discovery, RegenHU). Live/dead imaging was used to evaluate the cell viability after 3 days. 3D Printing an Anatomically Accurate Implant: μCT scans were used to determine the geometry of the lapine proximal humeral head. The implant was fabricated from a biodegradable polymer, polycaprolactone (PCL), using a FDM system (3D Discovery, RegenHU).

RESULTS & DISCUSSION: μtissues were successfully generated via SA using a range of starting cell densities. The diameter of these μtissues significantly increased with the addition of CDM+. Harvested cartilage spheroids were shown to SO after 2 days, forming interconnections which resulted in a unified neo-tissue. The viability of bioprinting as a means of spatially organising μtissues was demonstrated by maintaining cell viability post extrusion. Finally, a PCL implant, designed using medical images, has been 3D printed using FDM as a putative structural support for bioprinted μtissues.

CONCLUSIONS: Collectively, a high-throughput method for the generation of self-assembled chondrogenic μtissues, amenable to biofabricating scaled-up osteochondral tissues via bioprinting, has been demonstrated. The resultant construct is intended as a patient specific biological implant for total joint replacement.

INTRODUCTION: Finite Element (FE) modelling integrated with 3D bioprinting offers a powerful tool for the development of functional tissue replacements [1]. The aims of this study were to use FE models to design mechanically functional 3D printed polycaprolactone (PCL) scaffolds and to combine these with region-specific cell-laden bioinks to obtain a biphasic implant for osteochondral tissue engineering.

METHODS: The geometry of PCL scaffolds was modulated to obtain two designs with printed filaments that were either Aligned with the previous layer or offset in two planes (termed Double Offset). ABAQUS was used to develop FE models of the scaffolds. The compressive modulus and element fraction experiencing stresses greater than 17MPa (PCL yield stress) were predicted. To validate the FE model, scaffolds compressive modulus and permanent deformation was assessed experimentally. Biphasic implants were printed with two distinct PCL geometries: Double Offset for the chondral phase and a stiffer Aligned configuration for the osseous phase. The chondral phase was filled with a gelMA-alginate bioink containing a co-culture of MSCs and chondrocytes (3:1). The osseous phase was filled with a RGD-y irradiated-alginate bioink containing only MSCs. Constructs were cultured in media supplemented with TGF-β3 for 42 days. Biochemical, histological and immunohistochemical analysis was performed.

RESULTS & DISCUSSION: FE modelling of different PCL architectures was used to develop scaffold designs with compressive properties comparable to articular cartilage. The plastic deformation experienced by the scaffolds was also tailored. Computational predictions were verified experimentally. GelMA-alginate and RGD-y irradiated-alginate bioinks facilitated the bioprinting of a spatially defined osteochondral-like template. sGAG and collagen levels were higher in the chondral phase of the construct, with more evidence of mineralization and collagen type X observed in the osseous phase.

CONCLUSIONS: CAD based-FE models and 3D printing were successfully used to engineer cell laden, fibre reinforced composites with mechanical properties comparable to native tissues.

INTRODUCTION: Polyurethanes (PUs) are very tunable polymers due to the high versatility of their chemistry that allows the synthesis of materials with very different properties by simply changing their building blocks. With the final aim to design thermo- and pH-responsive hydrogels for injectable or 3D-printing applications, an amphiphilic PU was first synthesized and its powder were then plasma-treated in the presence of acrylic acid (AA) vapor to graft acid groups along polymer backbone.

METHODS: An amphiphilic PU was synthesized according to [1] and its powder with controlled diameter were plasma-treated with Ar and AA vapor to expose –COOH groups (P-PU), thus enhancing hydrogel sensitivity to alkaline pH. Chemical characterization was performed by Size Exclusion Chromatography (SEC), Infrared (IR) Spectroscopy, Toluidine Blue O (TBO) assay and Proton Nuclear Magnetic Resonance (1H-NMR). PU and P-PU gels (15% w/v) were characterized in terms of sensitivity to temperature (tube inverting and gelation time tests at 37°C, rheology) and external pH (hydrogel pH change in response to external pH, swelling test in contact with buffers at pH 5 or 8). Finally, an innovative investigation of hydrogel thermo- and pH-sensitivity was conducted by Low-Field NMR.

RESULTS & DISCUSSION: SEC and IR assessed the successful PU synthesis, while TBO assay, 1H-NMR and IR demonstrated the grafting of –COOH groups to PU chains and evidenced a high intra- and inter-synthesis repeatability of the plasma treatment. Tube inverting, gelation time and rheological tests showed the ability of both PU and P-PU solutions (15%w/v) to undergo a sol-to-gel transition at about 27 °C. However, frequency sweep tests showed different storage and loss moduli crossover frequencies at each analyzed temperature (58 vs 82 rad/s, 4 vs 6 rad/s and 0.25 vs 0.15 rad/s for PU and P-PU gels at 25, 30 and 37 °C, respectively), suggesting that the exposure of –COOH groups slightly slowed down gelation kinetics. Concerning sensitivity to basic pH, P-PU gels transferred alkaline pH from the external medium to the gel core with a significantly faster kinetics, resulting from an increased sensitivity of almost the 60% compared to PU gels. Conversely, both systems behaved similarly in the presence of acid buffers. Swelling test against an alkaline buffer confirmed the improved absorption ability of P-PU gels compared to the control (3.3% vs 1.1%, respectively). These results were further proved by LF-NMR that allowed the investigation of hydrogel structural changes at the micro/nano-scale in response to temperature and pH changes in terms of micelle nucleation and organization and their interaction with water molecules.

CONCLUSIONS: PUs are promising candidates for the design of stimuli-responsive hydrogels, as their properties can be easily tuned by changing their building blocks. In this work, stimuli-sensitive PU-based hydrogels were successfully designed and their thermo- and pH-responsiveness was thoroughly investigated.

INTRODUCTION: Biomimicry is an important principle underlying a number of tissue engineering (TE) strategies. Emulating the three dimensional (3D) hierarchical organization of physical and/or biochemical cues of the native cellular microenvironment is likely to be key to building scaffold materials with higher levels of functionality. Despite advances in TE, true 3D patterning of biochemical cues has proved difficult. Clay nanoparticle gels offer potential in TE for their ability to sequester proteins for sustained localized function. The current study reports a simple and biomimetic approach to applying self-assembling clay hydrogels for spontaneous 3D micropatterning of proteins under physiological conditions.

METHODS: Hydrous suspensions of Laponite, a synthetic smectite clay were added to a master solution containing defined concentrations of biomolecules and ions present in blood plasma to initiate a diffusion-reaction mediated self-assembly process. The structures were analysed using a range of microscopy techniques and tested for their ability to pattern model proteins (serum albumin, avidin, streptavidin, immunoglobulin G and casein) and localize the activity of bone morphogenetic protein in vivo.

RESULTS & DISCUSSION: Laponite/protein scaffolds possessed an internal degree of order able to template concentration gradients of fluorescently labelled model proteins. Characterization of the structures using confocal scanning laser microscopy demonstrated micron resolution control of 3D patterning according to assembly time, temperature and concentration. Non-self-assembled Laponite gel with blood plasma components adsorbed model proteins on gel surfaces. Polarized light imaging revealed radial birefringence patterns indicating a nanoscale periodical arrangement, which changes as function of time at physiological temperature. Scanning Electron Microscopy and rheological studies show rearrangement of the nanoparticle upon interaction with proteins. Scaffolds loaded with BMP 2 achieved formation of ectopic and localized bone in a murine subcut model.

CONCLUSIONS: This study reveals, for the first time, the possibility to harness interactions between clay nanoparticles, biomolecules and ions present in physiological fluids to trigger the assembly of supramolecular structures of physical and biochemical cues. This bottom up approach affords new opportunities for 3D protein micropatterning and delivery of growth factors for tissue engineering of hard and soft tissues.

¹Indian Institute of Technology (IIT) Hyderabad, India

INTRODUCTION: Currently used guided tissue regeneration (GTR) mainly act as barrier membrane to prevent down growth of epithelial and gingival tissue without any regenerative functionality, have limited success in the clinic. There is a need to develop new biomimetic, tissue adaptive nanofibers membrane for effective regeneration of periodontal tissues. Electrospinning, most common method of nanofibers fabrication suffers several limitations such as low deposition rate, costly equipment etc. Conversely, our recently developed coaxial airbrushing is a cost effective alternative to electrospinning overcoming its limitations, offering rapid fabrication of coaxial fibers directly on the target of interest with a simple set-up. The objective of this study is to develop a new multilayered (two layers) functional membrane, which not only act as barrier membrane but also promote specific periodontal tissues regeneration by providing microenvironment of chemical cues (Growth Factors; GFs), physical cues (nanofiber topography) and tissue adaptive degradation properties for potential GTR application.

METHODS: In-house built co-axial airbrushing technique was used to fabricate GFs encapsulated two-layer core-shell nanofiber composite membrane with core-shell nanofibers (PCL-PEO blends) of tailor degradation properties. Top layer loaded with bFGF has least porosity whereas bottom layer with VEGF+PDGF is highly porous to promote cell recruitment and migration. Composite nanofibers were characterized by various techniques. Release profiles of different GFs were measured using specific ELISA kits. Three different cells, human gingival fibroblast (HGF), HUVEC and hBMSC cells were used to test the biocompatibility properties as well as specific regenerative functionality of different membrane.

RESULTS & DISCUSSION: For the first time GF encapsulated multilayered nanofibrous scaffold was fabricated by coaxial airbrushing method. Core-shell composite nanofibers membrane shows sustained release of different GF (up to 30 days) to promote the specific biological response. Cells showed extended morphology and higher cell proliferation in GF loaded fibers as compared to control. Top layer promotes proliferation of HGF and showed limited penetration of cells into membrane. Bottom layer, promote proliferation, migration and differentiation of HUVEC and hBMSC.

CONCLUSIONS: This study confirms that the novel multilayer core shell nanofiber scaffolds, fabricated by airbrushing technique is biocompatible, cost effective and have huge potential for periodontal tissue regeneration.

ACKNOWLEDGEMENTS: Financial support was received from DST, Nanomission (SR/NM/-NS-1364/2014(G).

INTRODUCTION: The functional behavior of tendons is highly related with their ECM anisotropic alignment and hierarchical organization. As mechanosensitive tissues, the combination of tendon mimetic scaffolds with mechanical stimuli might synergistically contribute for their regeneration. We previously developed 3D fibrous scaffolds that induced stem cell tenogenic commitment and prevented the phenotypic drift of tenocytes [1]. We hypothesize that by combining it with superparamagnetic nanoparticles as remote actuators to mechano-magnetic stimulation, we can further boost their functional regenerative potential.

METHODS: Electrospun nanofiber threads were assembled into yarns and these into woven hierarchical 3D scaffolds [1]. The threads based on PCL were mechanically reinforced with cellulose nanocrystals decorated with iron oxide nanoparticles and coated with polydopamine grafted with hydrophobic dodecanethiol (DT-NP). The tenogenic commitment of hASCs cultured on the magnetic responsive systems was assessed.

RESULTS & DISCUSSION: Incorporation of DT-NP (0-5wt.%) significantly improved the mechanical properties of the nanofiber yarns, simultaneously endowing them magnetic responsiveness. Magneto-mechanical stimulation of hASCs promoted activation of the mechanosensitive pathway YAP/TAZ, increasing cell cytoskeleton anisotropic organization. As feedback, hASCs showed higher gene and protein expression of tendon-related markers, such as TNMD and SCX, when compared to non-stimulated conditions.

CONCLUSIONS: The engineered magnetic nanofiber yarns were able to mechanically stimulate cells by remote actuation. The scaffolds architecture and stimulation synergistically contribute to boost the tenogenic commitment of hASCs.

INTRODUCTION: By the growing expectations toward cellular products, the size and quantity of cells required for applications are exponentially growing. However, manufacturing process for cells for therapy comprises too many parameters that are still not clearly understood, therefore it is still difficult to control its consistency. Especially from the aspect of product quality control, cellular products are difficult to monitor its status to manufacture intact cells. In such situation, as the most practical and historical technique, cellular status monitoring had been achieved by manual microscopic observations. Our group has been proposing the combination of image processing and artificial intelligence (AI)-related machine learning for non-invasive cell quality evaluation technology to monitor cellular status for entire cell culture process [1, 2, 3]. Here we show that cellular morphological profiling guided by AI prediction can be applied to support the quality control of consistent cell manufacturing.

METHODS: Mesenchymal stem cells (MSCs), neural stem cells (NSCs), and induced pluripotent stem cells (iPSCs) are cultured under various conditions, and their phase contrast microscopic images were acquired with automatic image analysis system. Culture conditions were designed to mimic the cell culture failures. From the time-course cellular images, multiple morphological parameters were extracted as fingerprint signature. These parameters were then tagged with the experimentally assayed cellular status and applied to construct machine learning models.

RESULTS & DISCUSSION: By our multiple morphological parameter profiling, which reflects the heterogeneity of cellular population, the small differences between different cell culture conditions could be visualized. The constructed computational models which predicts the undifferentiation/differentiation status of cells were found to have high performances with different stem cell types. However, the most important point that was clarified through our investigation was that such performance of morphology-based quality evaluation by AI models were only achieved by collection technique for qualified and non-biased image data.

ACKNOWLEDGEMENTS: Our research was funded by the JST Program for Creating STart-ups from Advanced Research and Technology (START) program, and NEDO AI project.

INTRODUCTION: Many advances have been made in tissue engineering but challenges still exist for constructing thick or complex tissues with all in vivo functions. One of the main challenges is vascularization. In human body, cells are fed with nutrients and oxygen from capillaries located not further than 100-200 μm range. Therefore, skin constructs thicker than 200 μm have a diffusion limitation [1,2]. To address this issue, we developed a full perfusable vascularized reconstructed skin.

METHODS: Our technology consists of reconstructing the skin-equivalent in a culture device where nylon wires are strung across connectors to form molds inside a dermis-like layer composed of a mix of human fibroblasts and collagen hydrogel. Once hydrogel contracts, nylon wires are removed and channels are seeded with endothelial cells to form microvessels perfused with an external peristaltic pump. After human keratinocytes seeding, skin-equivalent can be lifted to air-liquid interface to allow the stratification of the epidermis [3].

RESULTS & DISCUSSION: Histological analysis and immunostaining of Collagen IV, Perlecan, CD31 and Vimentin showed that endothelial cells are organized in microvessels with accumulation of fibroblasts near microvessel structure. K14, K10 and Involucrin confirmed epidermis is correctly differentiated compared to normal human skin. The functional significance of the vascular structures was evaluated with fluorescent dextran diffusion.

CONCLUSIONS: After optimization of device’ surface treatment, fibroblast and endothelial cell concentrations, flow rate and media, successful development of a full thickness skin with perfusable microvessels was achieved. Perfusable skin models can be used for relevant systemic evaluation of actives and drugs in cosmetic and pharmaceutical research.

Mimicking the osteon structure by biofabrication techniques
Presenting Author: Sahar Salehi, sahar.salehi@bm.uni-bayreuth.de
1Department of Biomaterials, University of Bayreuth, Bayreuth, Germany

INTRODUCTION: Ink-printing has been used to deposit living cells, hydrogels (3D-ink) and other biomaterials in user-defined structures to build complex tissue constructs “as a bottom up approach.”[1] Natural cortical (compact) bone is composed of tightly packed units as concentric layers called osteons. Osteons are oriented parallel along to the axis of the bone and are made of mineralized collagen fibers around central Haversian canal, where vasculature and nerves are localized. The goal of this study was to mimic this 3D concentric layers “Osteon” using self-rolling constructs made of a composite hydrogel reinforced with bioceramics particles. The printed construct reinforced with particles will be able to provide mechanical stability and bioactivity which is required for the biomineralization of the system [2]. This platform can be further developed similar to the native osteon with vascular system and neuronal network.

METHODS: The nano particles of forsterite (Mg2SiO4) with high surface area were synthesized using sol-gel technique [2] and printing parameters and shape fidelity was evaluated using different concentration of hydrogel as well as particles concentrations (up to 5%wt nFo). Bioactivity of composite hydrogels, was also investigated during 14 days incubation in simulated body fluid (SBF) prepared according to Kokubo protocol [3]. Scanning electron microscopy-EDX, FTIR and elemental analysis was used for further analysis. The mechanics of the hydrogels were tested using rheometer.

RESULTS & DISCUSSION: The results showed by controlled crosslinking and optimized amount of particles up to 1 wt%, a flexible and elastic nFo-alginate printed structure is achievable. By increasing the amount of the particles the higher bioactivity was observed which was confirmed by higher apatite precipitations on the surface of cross-linked hydrogels during 14 days. The elemental analysis also confirmed the higher release of Mg and Si ions from the composite inks containing 5wt% nFo. These results shows the suitability of this composite as an effective bone graft substitute.

CONCLUSIONS: In conclusion, this study demonstrates optimization of material parameters for 3D printed nFo-Alginate scaffolds and enhancement of mechanical properties and bioactivity by incorporation of forsterite particles.

ACKNOWLEDGEMENTS: Funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – Projektnummer 326998133 – TRR 225 (subproject B03).

INTRODUCTION: There is growing interest in peripheral nerve interfaces (PNIs) to create long-lasting nerve/machine connection to improve prosthetic robotic limbs for amputees [1]. Undesirable chronic cellular responses to PNIs is a challenge that must be overcome. To improve PNIs function, we propose to use tissue engineering techniques that provide advanced microarchitecture to stimulate healthy Schwann cell (SC) migration and elongation while inhibiting fibrotic encapsulation in order to promote natural axonal regeneration. We designed various microtopographies including channels (CH) and Sharklet® (SK), and then screened them against fibroblasts and SCs in vitro. SK, inspired by the dermal denticles of shark skin, is effective at modulating the fouling response of a wide range of fouling vectors including bacteria, marine organisms, and eukaryotic cells [2].

METHODS: Silicon wafers were patterned containing the inverse of nineteen separate microtopographies with dimensions ranging from 2 to 20 μm using photolithography and etched up to 3.7 μm deep using deep reactive ion etching. Individual polyimide disks were formed by spin coating and curing polyimide (U-Varnish S, UBE Ind.) onto etched wafers and isolated from the cured film by O₂ plasma dry etching. Samples were adhered onto disk coverslips, placed in 24-well cell culture plates, sterilized, and seeded with either rat SCs or fibroblasts. Metabolic activities of the cells were assessed and quantified using Alamar blue Assay at day 1, 3, and 7 and compared to the smooth control (n=3). The cell cytoskeleton and cell nuclei were visualized and imaged to study the changes of the cell shape and morphology in response to microtopography shape and geometry.

RESULTS & DISCUSSION: Engineered microtopographies were characterized by profilometry and SEM (Figure 1). Cell proliferation was normalized against smooth controls, and results show a strong correlation between pattern dimension and geometry with a mix of inhibitory and promoting patterns. Interestingly SK 20×2 inhibits fibroblast adhesion and proletarian while promoting SC proliferation. Staining shows how cells are changing the shape of their body and nuclei in interaction with patterns.

CONCLUSIONS: In vitro, engineered microtopographies can control the cellular response of fibroblasts and SCs. SK 20×2 can be used to inhibit fibroblasts and promote SCs in PNIs. We also performed limited in vivo tests, which for future applications need to be expanded.

Poly ethylene(glycol) hydrogels to mimic the stem cell bone marrow niche
S. Donnelly¹, S. Trujillo-Munoz¹, E.R. Cross², E.R. Draper², M. Salmeron-Sanchez¹, M.J. Dalby¹
Presenting Author: Sam Donnelly, s.donnelly.1@research.gla.ac.uk

INTRODUCTION: Poly ethylene(glycol) (PEG) is a bioinert and biocompatible substance that can be used to form hydrogels for 3-dimensional cell culture [1,2]. By using PEG, we can control gel physico-chemical properties and composition, such as stiffness and degradability, through the addition of a degradable crosslinker. Fibronectin (FN) can also be incorporated into the gel aiding cell adhesion and binding growth factors (GFs). Here, we tested how these matrices capture GFs that are involved in maintaining the bone marrow stem cell niche, including C-X-C motif chemokine 12 (CXCL12), fms-like tyrosine kinase 3 ligand (Flt-3) and stem cell factor (SCF).

METHODS: Three different gel compositions were used to assess the retention of GFs over a period of 48 hours. PEG gel with no FN, PEG gel with FN and PEG gel with 25% degradable crosslinker and FN. All gels were made up to 50ul and were 5 wt. % 4-arm PEG maleimide with a PEG diThiol crosslinker and a custom-synthesised protease-degradable peptide crosslinker (GCRDVPMSMRGGDRCG, VPM peptide). GFs (CXCL12, Flt-3 and SCF, 10 µg/mL) were added to the gels before gelation, allowing them to be encapsulated into the gels.

RESULTS & DISCUSSION: Analysis of GF release using the Kruskal-Wallis statistical test illustrated some significant differences between PEG only gels and gels containing FN. When studying CXCL12 release, PEG only hydrogels released close to 100% of the CXCL12 initially added, whereas the condition of PEG with FN (p≤ 0.05) released around 70% of the GF incorporated. The release of Flt-3 showed similar results, where the PEG only condition did not retain any GF at 48 h but the PEGVPM with FN (p≤ 0.05) retained up to 50% of the Flt-3 encapsulated. For SCF release, PEG only hydrogels released 60% of the GF added and the PEG with FN only 40% (p≤ 0.01) at the same timepoint. Moreover, no differences were found when adding degradable crosslinker to the PEG with FN hydrogels for all three growth factors tested, suggesting that FN plays an active role in growth factor retention independently of the crosslinker added.

CONCLUSIONS: Collectively, these data clearly show the increased retention of GFs relevant to the bone marrow niche in gels containing FN.

INTRODUCTION: The efficient production of laboratory-manufactured reticulocytes (that differentiate into red blood cells in vivo) could provide an alternative source of blood for transfusion. The immortalized erythroid progenitor cell line BEL-A [1], is highly proliferative, can be gene edited to remove blood groups [2] and also differentiate into functional reticulocytes offering a potential sustainable reticulocyte source for in vitro manufacture. In this work, we have begun to engineer a fluidized bed bioreactor (FBB) system to culture and eventually scale up the expansion and differentiation of the BEL-A cells in vitro. FBBs are attractive bioreactor technologies due to their superior mass transfer characteristics compared to traditional stirred tank reactors and hollow-fibre systems [3].

METHODS: 1 – 3 x 10⁴ BEL-A cells/ml were cultured in suspension within FBB glass columns (10 and 25 mm internal diameter) and cell-culture media perfused (2 – 7 x 10⁻⁶ m s⁻¹) through the column to fluidize the cells. The fluid velocity at which the bed fluidizes was determined by measuring the change in the pressure drop across the bed of cells. The viability and differentiation of cells within the FBB were compared to static 2D culture. Viability was measured via Trypan blue-assisted cell counts and DNA measurements (Picogreen assay). Differentiation was assessed by measuring marker proteins GAP and Band-3 via flow cytometry. The dO₂ levels were measured using in situ oxygen sensors while glucose and lactate levels measured using HPLC.

RESULTS & DISCUSSION: Compared to the 10 mm column, the fold change in cell numbers was higher in the 25 mm column (5.8 vs 3.4 in 10 mm) although lower than in 2D static culture (6.7) after 5 days in culture. The larger column, for the same velocity of fluid flow to the 10 mm column, permits a higher flow rate (difference in surface area) and hence has improved nutrient and dO₂ supply. This promoted cellular proliferation and additionally reduced stimulating differentiation of the BEL-A cells towards the erythroid lineage.

CONCLUSIONS: By designing the FBB to culture BEL-A cells at the optimum cells per unit volume and reducing shear while maximizing supply of nutrient, it is possible to achieve higher proliferation with reduced induction of cellular differentiation. In addition, the design can be easily adapted for cellular differentiation whilst allowing easy harvest of the final cells of interest (reticulocytes). Future work will focus on optimizing the operating conditions to scale-up the manufacturing process.

ACKNOWLEDGEMENTS: The authors would like to thank NIHR funding of the Blood and Transplant Research Unit (NIHR BTRU) in red cell products (University of Bristol)

Janus 3D printed scaffolds for ultrasound stimulated bone regeneration
S. Camarero-Espinosa¹, L. Moroni¹
Presenting Author: Sandra Camarero-Espinosa, s.camarero-espinosa@maastrichtuniversity.nl
¹MERLN Institute for for Technology-Inspired Regenerative Medicine, Maastricht University, Maastricht, The Netherlands.

INTRODUCTION: Mechanical stimulation is known to promote an increased bone mass formation during fracture healing processes. Mechanical stimulation via application of ultrasounds is a clinically used method for this purpose [1]. However, healing of long fractures still requires the use of autologous tissue grafts. To overcome this issue we have fabricated self-assembled Janus 3D printed scaffolds from common biomaterials [2]. We hypothesized that these structures will behave as transducers, with a “reacting” and a “backing” material. Here, we report on the potential of these scaffolds as substrates to promote the differentiation of human mesenchymal stem cells (hMSCs) and the formation of bone.

METHODS: Polycaprolactone (PCL) and polylactide (PLA) were melt-blended at different ratios and their phase behavior upon 3D printing was analyzed by scanning and transmission electron microscopies. hMSCs were seeded at 10,000 cells/cm² on Janus scaffolds fabricated from a 50:50 PCL:PLA polymer blend and neat PCL and PLA scaffolds. hBMSCs were cultured for 7, 14 or 21 days under daily pulsed-ultrasound stimulation at 0, 15, 30 or 45 MHz during 30 minutes. hMSCs behavior was studied in terms of proliferation, matrix deposition and differentiation potential and the role of ultrasound stimulation in mechanotransduction was studied in terms of formation of focal adhesions.

RESULTS & DISCUSSION: 3D printing of PCL and PLA resulted in self-assembled scaffolds presenting different phases depending on the ratio of the polymers. At a 50:50 PCL:PLA Janus-fibered scaffolds were formed. Ultrasound stimulation of hMSCs seeded on Janus scaffolds showed an increased cell number dependent on the applied frequency. Stimulation at 45 MHz results in an increased cell proliferation, matrix deposition and osteogenic differentiation as shown by immunohistological and polymerase chain reaction (PCR) experiments. A study on the mechanism driving osteogenic differentiation of hMSC points out specific mechanotransduction pathways.

CONCLUSIONS: Our findings describe a method for the fabrication of Janus scaffolds and their utilization as bone regeneration platforms under ultrasound stimulation. A define mechanism driving cell differentiation is also proposed.

INTRODUCTION: Conductivity is a desirable property of an ideal Nerve Guide Conduit (NGC) that are being considered for use in peripheral nerve injury treatment. Most of the conductive polymers reported in use for fabrication of tissue engineering scaffolds such polypyrrole (PPy), polyaniline (PANI), polythiophene (PTh) and poly(3,4-ethylenedioxythiophene) (PEDOT) are non-biodegradable and possess weak mechanical properties to be fabricated into 3D structures [1]. In this study, a biodegradable and conductive block copolymer of PPy and PCL (PPy-b-PCL) was used to fabricate 3D porous NGCs using a novel Electrohydrodynamic Jet 3D Printing process.

METHODS: An in-house built EHD jetting system was used for the fabrication of scaffolds [2]. Three different concentrations of PPy-b-PCL (0.5%, 1% and 2% v/v) are mixed with PCL (70% w/v) in glacial acetic acid and fabricated into 3D porous scaffolds. Mechanical and material characterization of as printed scaffolds and the tubular conduits are done. In vitro accelerated degradation studies are also performed in order to determine the degradability of EHD-jetted PCL/PPy scaffolds. In vitro neural differentiation studies using hESC-derived neural crest stem cells (NCSCs) are also performed.

RESULTS & DISCUSSION: The mechanical properties of the scaffolds decrease with the addition of PPy-b-PCL. The yield strength of the NGC decreases from 12.95±1.26 MPa of that of pure PCL scaffolds to 5.02±1.68 MPa (PCL/PPy 0.5%) and 4.82±0.84 MPa (PCL/PPy 1%), which is closer to the properties of the native human peripheral nerve (~6.5 MPa). PCL/PPy 2% scaffolds are much weaker than the other scaffolds, which might be due to the viscosity changes due to higher concentration of PPy-b-PCL. Accelerated degradation studies showed that the highest PPy-b-PCL concentration scaffolds had a greater weight loss. In vitro neural differentiation studies using hESC-derived NCSCs showed that the PCL/PPy 1% scaffolds was the best in terms of neural differentiation, as quantified by RT-PCR studies and immunocytochemistry.

CONCLUSIONS: Collectively, these data clearly illustrate the beneficial effect of conductive PCL/PPy scaffolds in peripheral nerve injury repair.

INTRODUCTION: Hyaluronan (HA) molecular weight (Mw) present an important role in tumor invasiveness and metastasis [1, 2]. The reported trends are contradicting: in some cases, lower Mw species are associated with more invasive tumors [3], while other reports suggest that higher HA Mw are the culprit for the invasion. A possible reason for this contradiction can be due to the use of different models. Herein, we evaluated the impact of HA Mw in cancer invasiveness using core-shell hydrogels – a physiological relevant 3D model. We encapsulated MKN45 gastric cancer cells in the core of the hydrogel, composed by alginate and HA of different Mws, and evaluated the formation of cancer spheroids under a 3D environment.

METHODS: The core of the hydrogels (spheres) was made by a combination of alginate (Pronova VLVG, 20 mg/mL) and HA (of different Mws, i.e. 6.4, 752 and 1500 kDa, c=1mg/mL) and crosslinked with CaCl2 (100mM). We encapsulated MKN45 cells (at 5x10^6 cells/mL) during the processing of the core spheres, that were further embedded in an alginate disc (shell). Cell viability was accessed by live/dead staining using calcein (1.2 µL/mL) and propidium iodide (0.6 µL/min), respectively.

RESULTS & DISCUSSION: Cell viability analysis clearly shows a higher cell density in all mixed systems (combination of alginate and HA) as compared with the controls (only alginate). The increase of HA Mws induces a higher cell proliferation and formation of bigger cell clusters (spheroids).

CONCLUSIONS: We were able to correlate high Mw of HA with an increment on cancer cell viability and spheroid sizes (up to 150 μm for the HA of 1500kDa -measured in the Z axis). The presented data clearly illustrate the influence of HA Mw on tumor growth and in the formation of cancer spheroids.

INTRODUCTION: Platelet lysates (PL) are a human source of growth factors (GFs) and other bioactive proteins. Therefore, they have been explored for clinical and tissue engineering (TE) purposes [1,2]. Herein, we propose a novel human PL-based platform with tunable mechanical properties (PLMA) for human 3D cell culture.

METHODS: PLMA were prepared by mixing PL with methacrylic anhydride at different ratios. Two different degrees of modification were prepared (PLMA100 (low) and PLMA300 (high)) and fully characterized by NMR and Mass Spectrometry. Hydrogels were formed by irradiating with UV light a solution of PLMA containing 0.5% (w/v) of Irgacure 2959. Their structural and mechanical properties were assessed by SEM, compression tests and rheological studies. Release of proteins and GFs from these hydrogels was also evaluated. Biological assays were performed by encapsulating human adipose stem cells (hASCs) into PLMA hydrogels. Furthermore, PLMA sponges were formed after PLMA hydrogels freeze-drying and seeded with hASCs. hASCs were tested for cell adhesion, viability and proliferation.

RESULTS & DISCUSSION: PLMA hydrogels here proposed are easy to handle and show tunable mechanical properties that can be easily adjustable by changing PL degree of modification or PLMA concentration. hASCs were encapsulated and cultured for 7 days. Results showed that PLMA hydrogels support cell adhesion, growth and invasion within the 3D matrix. Immunocytochemistry analysis of hASCs at 7 days of culture shows no evidence of differentiation of hASCs encapsulated in PLMA hydrogels. PLMA sponges were seeded with hASCs and cultured for 14 days. Overall, for both PLMA hydrogels and sponges, hASCs exhibited high cell viability, adhesion and proliferation showing their potential to be used as a humanized 3D cell culture platform. Further, PLMA hydrogels showed sustained release of proteins and GFs.

CONCLUSIONS: These results showed that PLMA hydrogels are a promising platform for TE applications. The material here developed could have an autologous origin, being adequate to produce customized robust matrices with no risk of cross reactivity, immune reaction or disease transmission.

Liquid platelet-rich fibrin (i-PRF) enhances the vascularization of a non-crosslinked collagen matrix in vivo

INTRODUCTION: Vascularization is highly necessary for tissue regeneration [1]. Platelet-rich fibrin (PRF) is a blood-based concentrate system obtained from the centrifugation of peripheral blood without additional anticoagulants [2]. This system is clinically highly relevant and was developed to support regeneration in damaged tissues. In vitro studies proved that reducing the relative centrifugation force (RCF) during the preparation of PRF leads to significant enrichment of the matrices with platelets and leukocytes in addition to the significant increase of growth factor release [2]. The aim of the study was to investigate the influence of liquid PRF on the in vivo vascularization and integration of a non-crosslinked collagen matrix in vivo.

METHODS: Liquid PRF (i-PRF) was gained from human blood. The collected blood was immediately centrifuged at either high-RCF (966 g) or low-RCF (60 g) and applied on the collagen matrix. The resultant biomaterial PRF construct was subcutaneously implanted in severe combined immunodeficiency (SCID) mice (n=4 per group). For the control group, the biomaterial was rinsed in phosphate-buffered saline (PBS) and subcutaneously implanted. After 10 days, the implantation areas were analyzed histologically. Immunohistochemical staining and histomorphometrical analysis was performed for the vessel density using CD-31 for mice and the distribution of human inflammatory cells, expressing vimentin, CD-3, CD-20, or CD-68 in the implantation bed.

RESULTS AND DISCUSSION: The vessel density within the biomaterial was significantly higher in the case of low-PRF compared to high-PRF (P<0.001) and control-group (P<0.0001). Vimentin expression as a pan marker for human cells was highly expressed in the group of low-PRF, whereas no cells were found in the group of high-PRF. Thereby, the expression of human cell markers was significantly higher in the group of PRF-low compared to PRF-high and control-group (CD-3 P<0.001; CD-20 P<0.05 and CD-68 P<0.0001). Previous studies proved the angiogenesis effect of preculturing biomaterial using primary cells as a tool to enhance vascularization1. However, this concept is difficult to translate to clinical application. The present findings highlight the use of PRF as an alternative to primary cells to enhance the biomaterial vascularization. Centrifugation using low-RCF led to significant increase of the cell-mediated vascularization in vivo. This concept is highly relevant for clinical application because of its simple preparation and high potential for translation to clinical application.

CONCLUSION: The use of i-PRF as an autologous source of inflammatory cells and growth factors provides pro-angiogenic stimuli and supports biomaterial vascularization as a clinically applicable tissue engineering concept.

INTRODUCTION: Nowadays autologous fibroblast application for skin repair presents an important clinical interest. In most cases, in vitro skin cell culture is mandatory. However, cell expansion using xenogeneic or allogenic culture media presents some disadvantages, such as the risk of infection transmission or slow cell expansion. In this study, we investigated an autologous culture system to expand human skin fibroblast cells in vitro with the patient’s own platelet-rich-plasma (PRP).

METHODS: Human dermal fibroblasts were isolated from patients undergoing abdominoplasty and blood was collected to prepare fresh PRP using the CuteCellTM PRP medical device. Cultures were followed up to 7 days using a media supplemented with either fetal bovine serum (FBS) or PRP.

RESULTS & DISCUSSION: Fibroblasts cultured in medium supplemented with PRP showed dose-dependently significantly higher proliferation rates (up to 7.7 times with 20% of PRP) and initiated a faster migration in the in vitro wound healing compared to FBS, while chromosomal stability was maintained. At high concentrations, PRP changed fibroblast morphology, inducing cytoskeleton rearrangement and an increase of alpha-SMA and vimentin expression.

CONCLUSIONS: Our findings show that autologous PRP is an efficient and cost-effective supplement for fibroblast culture and should be considered as a safe alternative to xenogeneic/allogenic blood derivatives for in vitro cell expansion.

Figure 1: Assessment of PRP proliferative effect by flow cytometry using CellTrace Violet (vital dye). Proliferative effect of increasing PRP concentrations in comparison (1-50%) with FBS 10% (n=10 different patients) on NHDF for 7 days without medium change in a complete autologous system (cells and PRP from the same patient).
A therapeutic intraperitoneal reservoir (TherIP) and minimally invasive delivery system for regional, repeated intra-abdominal drug delivery

INTRODUCTION: Emerging technologies in the fields of regenerative medicine, cell therapy, gene therapy, and nanotechnology have broadened intraabdominal targets for multiple pathologies. However, maintaining a local therapeutic dose in deep tissue compartments while minimizing off-target effects remains a challenge. We previously developed a therapeutic reservoir for delivery to the heart [1]. The aim of this study was to develop a therapeutic intraperitoneal reservoir device (TherIP) and delivery system which enables targeted and repeated drug or cell delivery to the omentum in a large animal model through a minimally invasive procedure.

METHODS: The TherIP device was fabricated using porous thermoplastic polyurethane (TPU) sheets thermoformed into interconnected reservoirs. An acute pig study was used to validate device deployment and delivery system design. Devices were targeted to the omentum of 35 kg landrace swine under general anesthesia (n=3), after which animals were euthanized to confirm device placement.

RESULTS & DISCUSSION: The intraperitoneal space was accessed via a percutaneous approach using an over the wire technique. A custom designed delivery system consisting of coaxial 3D printed sheaths was used to position the TherIP device over the omentum using ultrasound and fluoroscopic assistance. The reservoir system was deployed and then fixed with a cyanoacrylate adhesive. A radiopaque hydrogel was injected through an inlet line to simulate filling with therapeutic cargo. All animals tolerated the procedure in an acute setting, and post-mortem examination confirmed placement of the device.

CONCLUSIONS: We have developed a soft, flexible, reservoir system for local, repeated drug or cell delivery to intraabdominal targets. The device can be deployed, fixed, and filled through a minimally invasive, percutaneous procedure with minimal complications.

INTRODUCTION: Chitosan nanoparticles (NPs) have great potential in nanomedicine; however, low solubility of chitosan severely limits their potential clinical translation [1]. Here, we present a systematic analysis to tune the size and zeta potential of NPs through both artificial neural network (ANN) model and experimental approaches to increase the solubility of chitosan NPs in physiological media. We use (i) PEG chain length, (ii) chitosan/PEG ratio, (iii) pH of solution as the three independent input variables. We utilize a novel, ultrafast and convenient method for the PEGylation of NPs through a photopolymerization along with ionic crosslinking. NPs with higher zeta potentials promoted adhesion of HEK293-T cells on NP-coated surfaces in cell culture medium, which was predicted through ANN. In summary, we present synthesis of PEGylated chitosan NPs through both ionic and covalent means, utilize ANN model as a tool to predict size and zeta potential which can capture cell adhesion behavior on surfaces prepared with these engineered NPs.

METHODS: HEK293-T cell line was used for cell culture experiments. Cells were seeded (10,000 cells/well) on 96-well plates and treated with altered concentrations of PEGylated chitosan NPs for 24 h and 48 h. Next, cells were incubated with shaking at 100 rpm using Cell Titer-Glo reagent and luminescence was measured using a plate reader (BioTek’s Synergy H1). TNBS assay was used to characterize the degree of PEGylation.

RESULTS & DISCUSSION: PEGylated chitosan was synthesized both through NHS-amine coupling chemistry and photopolymerization with TPP, PEG and methacrylamide chitosan (CSMA) with UV light. We synthesized chitosan NPs using 9 different types of PEGylated chitosan monomer through the reaction of positively charged chitosan and negatively charged TPP, formed polyelectrolyte complexes under rigorous stirring. We also used photopolymerization of CSMA ANNs could accurately estimate the size and zeta potential of different groups. We observed that 2 kDa PEG had the highest number of attached cells and uncoated sample had the lowest number of attached cells.

CONCLUSIONS: This study demonstrates fundamental aspects of PEGylated chitosan NPs and proves that NPs with the desired surface charge and size properties can be prepared in conjunction with the ANN model [2].

INTRODUCTION: Recently, 3D printing technology has come into prominence in biomedical applications. Three-dimensional (3D) scaffold design plays an important role in tissue engineering to mimic the host tissue and defect morphology. Thus, shape-memory polymers (SMP) are generally used for scaffold fabrication to obtain the desired morphology and structure. Among SMPs, thermoplastic polyurethane (TPU) is a biodegradable elastomer that is widely used for biomedical applications. However, TPU has low mechanical strength and biodegradability. These limitations can be improved blending with other polymers such as polylactic acid (PLA) which has good biocompatibility, high mechanical strength and biodegradability. In this study, it is aimed to fabricate PLA/TPU (1:1) blend to overcome the disadvantages of both polymers where PLA is used as hard segment and TPU is used as soft segment. However, these scaffolds generally do not provide the desired bioactivity and surface properties for tissue regeneration. Thus, biopolymer based porous layer was integrated in SMP scaffold. Highly porous and silica-based diatomite frustules were used as bioactive agent in chitosan-gelatin matrix. Hence, the main purpose of the study is to fabricate scaffolds for bone regeneration to mimic the composite structure of bone tissue at macro-nano levels. Diatomite particles were used to enhance bioactivity by inducing cell-material interaction at nano level and stimulating biomineralization on surface. Furthermore, SMP based bilayer scaffold can be fabricated in desired dimensions and easily replace bone defects by the help of its shape memory characteristic.

METHODS: Bilayered scaffolds were fabricated with two different methods and layers were combined. Outer layer TPU/PLA was fabricated with 3D printing and chitosan-gelatin porous layer was obtained with freeze-drying. Layers were integrated successfully. Shape memory effect of TPU/PLA blend as 3D layer was investigated. Scaffolds were characterized with SEM, Micro-Ct., swelling, mechanic tests. Open porosity of scaffolds were determined with liquid displacement method. In vitro bioactivity of scaffolds was evaluated with Saos-2 cell line and cell proliferation and osteogenic markers as ALP, osteocalcin and biomineralization were investigated. Cell attachment on each layer was observed with SEM analysis.

RESULTS & DISCUSSION: Fabricated bilayer scaffolds showed shape memory characteristic and desired bioactivity with diatomite incorporation which improved the cell-biomaterial interaction. Scaffolds provided desired porosity levels and pore size range for bone tissue formation. In vitro results indicated that Saos-2 cells proliferated on scaffolds at desired level and secreted osteogenic markers during incubation. Bioactive porous inner layer induced biomineralization of scaffold.

CONCLUSIONS: In conclusion, bioactive natural polymer and SMP based bilayered scaffolds showed potential for bone tissue regeneration. This scaffold design for the bone tissue regeneration can be used in osteochondral defects by taking advantage of its different mechanical properties and morphology.
INTRODUCTION: The surface-selective laser sintering (SSLS) is a universal method which allows to create three-dimensional structures from polymer materials including FDA approved [1-2]. Herein, we assessed the potential of SSLS for creating scaffolds with prolonged drug release.

METHODS: The antifibrotic substance – pirfenidone was mixed with polylactide powder (PDL 04, PURAC) at the ratio of 600 µg/g, respectively. Next, the mixture was treated with scCO₂ (T=40 °C, P=140 MPa, τ=8 hours) in order to evenly impregnate the drug agent in the polymer volume. The resulting material was then ground to powder in a knife mill to obtain particles size less then 100 µm. Finally, the polylactide loaded with pirfenidone was used to design scaffolds with the dimensions 10×10×1 mm by SSLS method. Passive in vitro drug release was analyzed by the spectrophotometric method described in [3]. The obtained scaffolds were subcutaneously implanted into the ventral side of the rabbit ear cartilage plate (n=6). After 60 days of the implantation, the explants were collected for histochemical analysis.

RESULTS & DISCUSSION: Using SSLS method, we fabricated PLA scaffolds impregnated with pirfenidone. The impregnation was achieved with the aid of scCO₂. Passive in vitro drug release study did not reveal burst release in the first few hours. It is known that implantation of polylactide matrices is complicated by the formation of a surrounding fibrous capsule. The encapsulation of the scaffold with pirfenidone inhibited the capsule formation. In details, after 60 days of the implantation, strong fibrosis was observed in the control scaffolds (without loaded drug), while the pirfenidone-loaded scaffolds showed no evidence of fibrosis.

CONCLUSIONS: The obtained data shown that the SSLS method can be used to form three-dimensional polymer structures loaded with drug. In the future, it is planned to create structures with loaded drugs that allow not only to prevent fibrosis, but also leveling all the negative reactions of the body during implantation.

INTRODUCTION: Keratinocyte culture and self-assembled skin substitutes (SASS) have greatly improved the treatment of patients with severe burns. Currently, to properly culture human keratinocytes, fetal bovine serum (FBS) must be added to the medium. However, FBS exact biological composition is undefined and variations occur from batch-to-batch. FBS is also associated with a risk of xenogeneic pathogen transmission. For these reasons, discarding FBS usage in research and clinical contexts is desirable. Therefore, we aimed to develop a defined medium optimized for keratinocyte expansion and SASS production.

METHODS: Using a fractionated factorial design of experiment, we identified and optimized the concentration of a set of molecular factors capable of replacing FBS for keratinocyte culture, and produced our keratinocyte defined medium (DM). We compared the effects of this new medium to the serum-containing medium on keratinocyte cultures and SASS at the cellular and molecular levels.

RESULTS & DISCUSSION: Keratinocytes cultured in DM presented similar morphology and increased proliferative potential when compared to those cultured in FBS-containing medium. Transcriptomic profile analyses with RNA microarrays on 4 distinct cell populations cultured in either media revealed that only 0.16% of targets were differentially expressed. Most of the genes underexpressed in DM were associated to keratinocyte differentiation. SASS produced with either media were similar at the histological and mechanical levels. Additionally, SASS similarity was further confirmed with immunolabelling of various structure, adhesion, proliferation and differentiation biomarkers (Fig. 1). We also grafted SASS produced with either media onto athymic mice. For up to 6 months, the epidermis of SASS produced with DM regenerated, which confirms the presence of epithelial stem cells in the grafts.

CONCLUSIONS: In conclusion, this new defined medium is promising for keratinocyte culture and SASS production for research and clinical purposes.

INTRODUCTION: Musculoskeletal injuries are increasing in human and equine species. Cell sheets preserve the extracellular matrix (ECM) complexity, overcoming the problems derived from scaffolds [1]. However, the delayed in vitro ECM deposition is the biggest handicap for these therapies. Some polymers produced by several organisms in vivo appear associated to a great number of water molecules in solution, promoting a volume exclusion effect that enhances the ECM deposition in cultures. Also known as macromolecular crowding (MMC) phenomenon [2]. Herein, the MMC-related properties of a natural polymer (hyaluronic acid, HA), in comparison to Ficoll™ and carrageenan (CR) [3], were analysed.

METHODS: Equine adipose and bone marrow mesenchymal stem cells (MSCs) were seeded at 15,000 cells/cm² and WS-1 human dermal fibroblasts (hDFs) at 25,000 cells/cm². The media was supplemented with 100 μM L-ascorbic acid phosphate. Different concentrations of diverse HA molecular weights (MWs) were tested. SDS-PAGE, densitometry analysis and immunocytochemistry were conducted to detect ECM molecules deposition after 3, 5 and 7 days. Overall statistical significance was established at a p-value ≤ 0.05 by ANOVA one way analysis.

RESULTS & DISCUSSION: Densitometry analysis was performed to evaluate collagen type I α1 and α2 chains intensity for quantification. Some concentrations of the studied MWs corresponding to 60, 100, 500 and 1,000 KDa were significant in MSCs. However, HA-10 KDa was discarded from the study due to cell detachment. In contrast, PX did not promote collagen I deposition in WS-1 hDFs. However, HA induced collagen III deposition in WS-1 hDFs, being higher than Ficoll™ and CR. The highest collagen type I enhancer was CR (at 75 μg/ml) in all cell types. Equine MSCs were characterized by trilineage assays and FACS analysis; according to the current criteria for horse MSCs. CR did not alter the expression of the markers: CD29, CD44, CD105, CD90 and CD34.

CONCLUSIONS: HA has potential as MMC, enhancing collagen type I and type III deposition. Further studies will be needed to improve these PX properties.

ACKNOWLEDGEMENTS: This project has been funded by the European Union, Horizon 2020 Programme, under the Marie Skłodowska-Curie Actions, Innovative Training Networks, Grant Agreement 676338.

INTRODUCTION: Failure of tissue engineered (TE) constructs following implantation is one of the most challenging problems of tissue engineering. Thus, ensuring rapid vascularisation is considered as crucial for translation of TE constructs to the clinic. Functionalisation of the TE scaffolds with proangiogenic factors is a promising approach in order to overcome slow neovascularisation. Vascular endothelial growth factor (VEGF) is recognised as the gold standard for promoting angiogenesis but it is also unstable, expensive and the use of high doses of VEGF can result in leaky immature vessels in vivo. The aim of this study is to develop E2 and 2dDR releasing biodegradable scaffolds and assess their potency for promoting angiogenesis.

METHODS: We first assessed the angiogenic potency of 2dDR and E2 versus VEGF in an ex-ovo chick chorioallantoic membrane (CAM) assay. Both factors were then electrospun into PHBV fibres. Sustained releases of both agents were observed over 30 days from these scaffolds using a spectrophotometric method. The proangiogenic activities of the drug releasing scaffolds were assessed using ex-ovo CAM assay. Finally, a 20% solution of lens culinaris agglutinin (LCA) was injected into the circulation of CAM to visualize the microvasculature.

RESULTS & DISCUSSION: Both E2 and 2dDR were found approximately 80% as potent as VEGF in stimulating new blood vessels in CAM assay when applied directly onto CAM. Both factors were found to be effective at stimulating neovascularisation over 7 days when released from fibres. The structure of microvasculature of CAMs and the vascular areas showed that an endothelial cell hypertrophy together with smaller lacunae compared to PBS can be observed for VEGF, E2 and 2dDR groups.

CONCLUSIONS: We conclude that both 2dDR and E2 provide attractive alternatives to VEGF for the functionalisation of TE scaffolds to promote angiogenesis. The gradual release of E2 and 2dDR from fibres stimulated the formation of new blood vessels in the ex-ovo CAM assay.

INTRODUCTION: Regeneration of bone with tissue engineering approaches is a promising way in order to reconstruct the bone defects without conflicting with side effects of bone grafts. Cell seeding, scaffold and signaling are three building blocks for regeneration of new bone. Intact human amniotic membrane, as a pre-formed sheet of stem cells, can be a proper candidate for osteogenesis which provide both seeding cells and scaffold together. [1]. Furthermore Bone morphogenetic protein-9 (BMP-9) and small molecule phenamil can induce osteogenic differentiation. [2, 3]. The objective of this study was to determine the synergistically effect of BMP-9 and phenamil on osteogenic differentiation of intact human amniotic membrane.

METHODS: In-situ differentiation of intact human amniotic membrane has been performed using four osteogenic media in four groups compared with control medium in 28 days. Basic osteogenic media was chosen as first group and the other three osteogenic media were made by addition of BMP-9, phenamil and BMP-9 alongside phenamil to basic osteogenic media in the second, third and fourth group, respectively. Alkaline phosphatase (ALP) activity, RUNX2 mRNA expression, Osteocalcin (OCN), Osteopenin (OPN), mineralization and calcium content were evaluated and compared among groups.

RESULTS & DISCUSSION: Addition of BMP-9 to basic osteogenic media had significant effect on mineralization and calcium content of amniotic epithelial cells. Furthermore, small-molecule phenamil changed the amount of RUNX2 mRNA expression significantly. Interestingly, addition of BMP-9 alongside phenamil to Basic osteogenic media had synergistic effect on osteocalcin, osteopnin and Alkaline phosphatase activity.

CONCLUSIONS: This study showed that utilization of BMP-9 alongside small-molecule phenamil can synergistically induce osteogenic differentiation of stem cells within intact human amniotic membrane which have resided in their natural environment.

INTRODUCTION: Design and construction an ideal decellularization bioreactor to obtain an intact liver scaffold can be of great help in regenerative medicine for the recovery of injured liver. The main reason of the damages to the scaffold during the decellularization process is mechanical stresses and prolonged exposure of the liver with decellularization agents. Therefore control of the pressure level and flow rate of solutions during decellularization process lead to the reducing mechanical damage to the scaffold structure, as well as effective penetration of the chemical agents into the depth of the tissue and clearing it in a shorter time.

METHODS: The built-in bioreactor has a seal main chamber with two inlet and an outlet valves, which provide a flow of cell removing solutions by using a constant pressure pump with a suitable flow rate. The Rat whole liver decellularization process was carried out with pressure of 50, 100 and 200 Psi. The structure and composition of decellularized organ were investigated using of SEM, staining with H&E, Van Gieson and Masson trichrome, amount of DNA content, IHC.

RESULTS & DISCUSSION: The results of the assessments revealed that the applying of constant pressure 100 Psi for whole liver decellurization compared to the other pressures resulted in minimal damage to the structure of the scaffold. The vascular network of the liver and its ECM structure, such as sinusoids, remained intact. Also, the amount and composition of ECM proteins such as collagen type 2, 3, 4, laminin and GAG’s are more similar to the normal liver.

CONCLUSIONS: The results of this study show that the optimization and utilize of constant pressure bioreactors plays an important role in the successful decellularization of whole liver. The applying of this method leads to obtaining of intact decellularized liver scaffolds by an appropriate combination in a shorter time.

Bilayered, non-cross-linked collagen matrix for regeneration of facial defects after skin cancer removal: a new perspective for biomaterial-based tissue reconstruction

Presenting Author: Shahram Ghanaati, shahram.ghanaati@kgu.de
Frankfurt Orofacial Regenerative Medicine (FORM) Lab, Department for Oral, Cranio-Maxillofacial and Facial Plastic Surgery, Medical Center of the Goethe University Frankfurt, Frankfurt am Main, Germany

Introduction: Skin cancer resection results in a skin defect of different dimensions. In the reconstructive surgery skin transplants are considered as the golden standard. However, this intervention is accompanied by various disadvantages such as extended operation time, additional wound and pain. The aim of this case series was to evaluate the biomaterial-based skin regeneration using a three-dimensional collagen matrix of porcine origin.

Methods: The three-dimensional bilayered collagen matrix was originally developed for intraoral applications. In the course of a translational research series, the matrix was first evaluated during a preclinical study. The membrane was subcutaneously implanted in CD-1 mice for 60 days to evaluate the cellular reaction using histological and specific immunohistochemical methods to identify the inflammatory pattern. In a second step the matrix was evaluated in two independent clinical studies with different indications i.e. tooth recession coverage and vestibulopathy. These studies included histological evaluation of the treated region. Finally, the matrix was used for the regeneration of skin defects (up to 8 cm), which was resulted from skin cancer resection (basal cell carcinoma and malignant melanoma; n=30). The regeneration process was photo documented and analyzed using specific visual scores (three independent surgeons). Biopsied from 10 patients were evaluated histologically and the cases were followed for three years.

RESULTS & DISCUSSION: Preclinical: the matrix gets integrated into the implantation area and preserved its integrity over 60 days without any signs of a foreign body reaction. Clinical intraoral application: tooth resection coverage was achieved in all cases and vestibulopathy was successful without adverse events. In extraoral application Clinical extraoral application: defect regeneration was achieved in all cases and the original contour and texture of the skin was reconstructed to a large extent. Histological biopsies of the intra- and extraoral application shows the integration of the membrane as a scaffold to guide the newly formed tissue to regenerate the defect.

INTRODUCTION: Duchenne muscular dystrophy (DMD) is caused by the almost complete absence of dystrophin protein due to out-of-frame mutations in the DMD gene. Antisense oligonucleotides (AONs) exon-skipping is one of the most promising therapeutic strategies for treating DMD, designed to skip a specific DMD exon, which produces a shortened transcript but a functional dystrophin protein. Here we designed a biomaterial strategy for encapsulation of therapeutic AONs in PEG-fibrinogen (PF) hydrogel-based microspheres as a controlled release system that can improve the pharmacokinetic properties of the AONs, increase their stability and greatly decrease the overall administered dosage.

METHODS: AONs loaded PF microspheres were formed using a dual photo-initiator, water-in-oil emulsion method. Prior to encapsulating, AONs were complexed with PEI, used as a transfection reagent. C2C12 mouse myoblasts were cultured and plated in 24 well plate. Cells were transfected with PF microspheres, each well contained 1 µg of 6-FAM labeled AONs and were incubated for 72 hours. The cellular uptake of AONs released from the microspheres was analyzed using confocal microscopy. For evaluation of dystrophin expression in mdx mice, isolated myotubes were cultured and dystrophin immunolabeling was performed after treatment of PF microspheres.

RESULTS & DISCUSSION: Figure 1 shows fluorescently 6-FAM labeled AONs loaded PF microspheres fabricated by the dual photo-initiator emulsion method, demonstrates spherical microspheres with encapsulation and homogenic distribution of the AONs within the PF hydrogel (i). In addition, penetration studies revealed that AONs polyplexes released from the microspheres and penetrated into C2C12 myoblasts after incubation of 72 hours (ii). For evaluation of dystrophin expression, mdx mouse isolated myoblasts treated with PF microspheres and immunostained with dystrophin antibody showed positive dystrophin expression (iii) compared to the untreated group.

CONCLUSIONS: PF hydrogel microspheres were able to release the therapeutic AONs, which demonstrate cellular uptake and successful restoration of dystrophin in vitro.

Figure 1: (i) Fluorescence microscopy of PF microspheres loaded with 6-FAM labeled AONs. (ii) AONs penetration study: transfection of 6-FAM labeled AONs into C2C12 myoblasts after 72 hours of incubation with PF microspheres encapsulating 1µg AONs per well. Introduction: Shortly after wound occur, platelets play important roles such as releasing growth factors from its alpha granules to initiate the wound healing process. This mechanism has been adopted in vitro condition by activating human platelet cell through freeze-thaw cycle to release the growth factors, then this cocktail is called as human platelet lysate (hPL). Efficacy of hPL has been widely used for cell culture medium and wound treatment in combination with bioscaffolds. In clinical fields, chronic wounds usually need months of treatment. An effective and efficient long-term preservation method of hPL is necessary to support its use in clinical setting. Some proteins are known stable for long-term preservation at 4°C after being lyophilized. Besides, we can use lyophilization process to adjust the concentration of hPL.

Methods: As biodegradation of hPL alone is short, we impregnated hPL into gelatin hydrogel (GH) before apply it as wound treatment. Full-thickness wound of male C57Bl6J/Jcl mice was used as the wound model. We considered 9 months are necessary as the period for long-term preservation. We compared cryopreservation of liquid form at -80°C and refrigeration of lyophilized form at 4°C. After being lyophilized, reconstitution with saline was adjusted to produce 1-fold, 2-fold and 3-fold concentrations of hPL. We use ELISA to measure quantity of growth factors in hPL. Histologic examinations using hematoxylin-eosin, Azan and anti-CD31 staining were performed on days 4, 7 and 14 to assess the wound healing process.

RESULTS & DISCUSSION: Concentration of PDGF-BB, VEGF, and TGF-β1 elevated in line with the concentration of hPL. From histologic examinations, neither the GH itself nor the simple administration of hPL accelerate the wound healing process. However, the combination of GH with 2-fold or 3-fold concentration of hPL accelerated the capillary and granulation tissue formation. In addition, the GH sheet impregnated with 3-fold concentrated hPL had the longest epithelium formation from the wound margin. There are no significant differences in the efficacy between preservation methods of hPL after 9 months.

CONCLUSIONS: Human platelet lysate in 2-fold or 3-fold concentration is effective to support wound healing in combination with gelatin hydrogel. Activities of the growth factors inside lyophilized human platelet lysate are maintained at 4°C for up to 9 months. This finding proposes a new long-term preservation method for human platelet lysate in clinical setting.
Opto-electrical fiber for real-time optical stimulation and electrochemical detection of dopamine exocytosis

INTRODUCTION: Parkinson’s disease (PD) is characterized by the degeneration of dopaminergic neurons in the midbrain leading to a dopamine deficit. Continuous delivery of dopamine has shown to reduce the risks associated with chronic motor complications. Here we describe a leaky opto-electrical carbon fiber as a potential neural implant for continuous supply and real-time modulation of dopamine in striatum using stem cells, optogenetics and electrochemistry.

METHODS: The polymer buffer layer on a commercial optical fiber was pyrolysed at 900 °C to obtain a carbon layer around the optical fiber. Pyrolysed carbon has proven to be biocompatible and to enhance the differentiation of human neural stem cells (hNSCs) into dopaminergic neurons. The carbon-coated optical fiber was made leaky using laser micro-ablation. Optogenetically modified hNSCs were cultured and differentiated in vitro on the fiber for 11 days (Figure 1a).

RESULTS & DISCUSSION: Figure 1b shows the initial amperometry results obtained first from potassium-induced depolarization followed by optical stimulation using blue light (460 nm). The peak heights are a direct measure of dopamine exocytosis from the cells. By comparing the current peaks, we see dopamine release from a large number of optogenetically modified dopaminergic neurons in the population. This dopamine can regulate physiological dopamine levels in the brain.

CONCLUSIONS: These initial results provide the first proof of concept for continuous real-time monitoring of dopamine release from stem cells cultured on the opto-electrical carbon fiber and its potential for use as PD therapy.

Figure 1: (a, left) Immunohistochemistry of opto-genetically modified hNSCs cultured on the fiber (Red: Tyrosine hydroxylase, Green: beta-tubulin, Blue: Nuclei). (b, right) Amperometry results showing chemical followed by optical stimulation.

Department of Materials Science and Engineering, National Tsing-Hua University, Hsinchu 30013, Taiwan

INTRODUCTION: Recent studies have shown that host non-inflammatory myeloid cells mediate the blood perfusion of engraftment of bioengineered vascular networks[1,2,3], so developing a biomaterial to regulate host myeloid cells into biomaterials and control the interaction between biomaterial and non-inflammatory myeloid cells could control the vasculogenesis and angiogenesis. In this study, we developed the hydrogel with different crosslinkable bonds to control the interaction between biomaterial and non-inflammatory myeloid cells, and regulate stem cell-based perfused blood vessels formation.

METHODS: There are two different collagen hydrogels. One is “Acid collagen hydrogel” formed by self-assembly collagen fibrils, and the other one is “Collagen-Ph hydrogel” formed through covalently cross-linked collagen fibrils. 200 μL of a mixed solution of collagen-Ph, enzyme horseradish peroxidase (HRP), and hydrogen peroxide (H2O2) or acid collagen hydrogels with the same mechanical properties G’~50 Pa mixed with endothelial colony-forming cells (ECFCs), and mesenchymal stem cells (MSCs) (2 x 10^6 total; 40:60=ECFCs: MSCs) was subcutaneously injected into nude mice before gelation. At the indicated time point, each implant was excised, fixed, embedded and immune-stained for various antibodies.

RESULTS & DISCUSSION: We compared the extent of vascular network formation in Acid collagen with Collagen-Ph. Acid collagen contained an extensive perfused blood vessels, and lumens expressed hCD31(human endothelial cells markers), confirming the human nature of the endothelium. By contrast, in the Collagen-Ph remained it organized as cellular cords on day7. To examine the role of myeloid cells in vasculogenesis, we further stained Ly6G (neutrophils markers), and CD45 (myeloid cells markers), the result show that the neutrophils-induced inflammatory time in Acid collagen was only two days, but in the Collagen-Ph it lasted four days. Collectively, these results confirmed that inflammatory time of Ly6G+ neutrophils are effect on the ability implanted human stem cell to enable formation of vasculature in vivo.

CONCLUSIONS: We demonstrated that crosslinkable bonds of hydrogel play an important role in controlling the interaction between host myeloid cells, implanted stem cells (ECFC and MSCs) and hydrogel, to further modulate the bioengineering vascular network formation in vivo. Therefore, how the crosslinkable bond of hydrogel regulate the mechanism and interaction between inflammation and vasculogenesis was constructed and discussion.

INTRODUCTION: Follistatin (FST) is a glycoprotein able to bind irreversibly to activin A, a protein that has been reported to inhibit bone formation. There are two FST variants (FST288 and FST315) with major differences in their ability to bind to the cell. This variation may influence their effect on bone repair. We investigated the effect of FST in critical processes for bone repair, such as cell recruitment, osteogenesis and vascularization, and ultimately its use for bone tissue engineering (TE). To do so, both FST variants were loaded in an in situ gelling formulation made by alginate and recombinant collagen-based peptide microspheres and implanted in a calvarial defect model.

METHODS: FST was added to the cell culture at a dose range (25-175 ng/ml) to study its effect on: MSC and EC migration; vascularization using tube-formation and spheroid-sprouting assays upon ECs; and MSC and pre-osteoblast osteogenic differentiation. The release profile of both FST variants from the alginate-based hydrogel was studied over 4 weeks. For in vivo studies FST315 and FST288 were loaded in the formulation and implanted in a calvarial defect model. Rats were scanned biweekly for 10 weeks. 4 Weeks postoperative, rats were subcutaneously injected with calcein. Samples were processed for histological evaluation.

RESULTS & DISCUSSION: FST stimulated MSC migration at all doses tested (P<0.01) and EC migration at 70 ng/ml (P<0.05). FST promoted tube-formation and sprouting at 28 ng/ml (P<0.05). FST did not enhance osteogenic differentiation of MSCs, but increased pre-osteoblast mineralization at all tested doses (P<0.01). Most of the loaded FST315 was released over 4 weeks, contrary to FST288, which was mostly retained in the formulation (P=0.0003). However, although a more homogenous mineralization progression was observed in the FST-treated samples, overall mineral density did not differ from the controls.

CONCLUSIONS: FST may be an early player in bone formation, having an angiogenic role and indirectly triggering ECM mineralization. Therefore, FST burst release could be necessary to trigger bone formation and its continuous release might not match with the pharmacokinetics of the protein. This is the first study that investigated the use of FST as a bone tissue engineering-based therapy, assessing protein’s effect both in vitro and in vivo. We have shown that FST stimulates, in vitro, essential processes for bone regeneration such as EC and MSC recruitment, formation and expansion of the vasculature and osteoblasts mineralization. Mechanistic studies are needed to clarify the biological activity of FST, and to further assess its potential and the most suitable FST carrier for bone tissue engineering applications.

INTRODUCTION: Cell based therapies gained increasing interest for the treatment of musculoskeletal tissue and injuries or degeneration. Herein, we propose that functional regeneration of these tissues can be achieved by using native capacity of cells to create their own tissue-specific extracellular matrix (ECM) avoiding the use of biodegradable scaffolds [1]. Cell culture on polystyrene and similar surfaces represents an artificial environment with differs substantially from natural in vivo microenvironment of the respective cells. One important factor is the dilute media composition. Macromolecular crowding (MMC) has been reported to dramatically increase the ECM deposition in vitro. We propose the noncarbohydrate single crowder PVP as a promising candidate for tissue engineering applications [2].

METHODS: In this work four commercially available non carbohydrate polymers, a) polyvinylpyrrolidone (PVP) 40 kDa, PVP 55 kDa, PVP 360 kDa and PVP 1300 kDa were used as crowding agents. WS1 fibroblasts were expanded up to passage 4 in DMEM media, supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin. 25,000 cells/cm ² were subsequently cultured for up to 7 days. Cell viability and metabolic activity and proliferation were accessed using Live/Dead, alamarBlue® and PicoGreen™ assays respectively. Extracellular matrix deposition was assessed with immunocytochemistry and sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE).

RESULTS & DISCUSSION: SDS-PAGE and densitometric analyses illustrated significant increase (p < 0.001) in collagen deposition in the presence of PVP grade crowder at all time points. Immunocytochemistry and relative fluorescence intensity analyses showed significant increase (p < 0.001) in collagen type I, deposition in the presence of PVP grade crowders. MMC did not affect cell proliferation and metabolic activity at all timepoint.

CONCLUSIONS: Mutually, these data clearly illustrate the positive effect of MMC in WS1 fibroblast cell culture.

INTRODUCTION: The wound healing process is a complex mechanism in which many factors are involved. The various properties of the amniotic membrane (AM) such as antibacterial and anti-inflammatory effects, non-immunogenic characteristic, and the ability to promote re-epithelialization make it an excellent wound dressing. In this study, we aimed to assess the effect of co-application of freeze-dried amniotic membrane and Lacto-n-Neotetraose (an inducer of type 2 immune response) in the treatment of full-thickness wounds in the mice model.

METHODS: The placenta samples were obtained from the donors under the cesarean section. Then, the AM was separated from chorion and freeze-dried under vacuum condition using vacuum freeze-drying apparatuses. The full-thickness wound model was created by punch biopsy with a 6mm diameter on the dorsal region of mice. Experiments were performed in 3 groups including G1 (wound with no wound dressing), G2 (wound covered by FDAM) and G3 (wound covered by AM/ LNnT (200 µg)) at four postulated times including 3, 7, 14, and 21 days post-surgery. The wound closure rate was compared in the three groups at the mentioned times. After sacrificing the mice, the wound samples were collected for histological and molecular analysis including H&E and Masson's trichrome stain and measuring the gene expression rate of Collagen I, III, VEGF-a, IL-4, IL10 and IL-13 using real-time PCR.

RESULTS & DISCUSSION: The wound closure rate in the G3 group was significantly higher than the G1 group at day 3 and G1 and G2 groups at day 7. H&E staining revealed that the epithelialization rate in the G3 group was better than the other groups at day 3. The epithelial layer was completely formed in G3 group at the day 7 while this condition was not observed in the G1 and G2 groups at the mentioned time. Also, the hair follicle was higher in the G3 group at days 14 and 21 in compared with G1 and G2 group. Masson's trichrome staining showed a better collagen deposition in G3 group than the two other groups which was in line with data obtained from the molecular analysis where the gene expression rate of col I and III was higher in the G3 group. An increase in gene expression rate of IL-4, IL10 and IL-13 showed that the use of LNnT could induce the type 2 immunity in G3 group.

CONCLUSIONS: Our results showed that the simultaneous use of LNnT with AM shows more positive outcomes than using amniotic membrane alone in wound healing.

INTRODUCTION: Ligament disorders and injuries are among the most common health problem influencing the adult population. To overcome problems related to autografts and allografts for ACL (anterior cruciate ligament) repair, tissue engineering (TE) could be a valid alternative strategy using scaffolds able to recruit cells while exerting the necessary biomechanical functions. An ideal scaffold for ACL TE (as well as for all other tissues) has to combine appropriate physical, mechanical and biological properties [1]. We present here the design and fabrication of a multicomponent scaffold with silk fibers in a porous silk sponge having the role of recruiting cells and host the regenerative pathway, whose mechanical properties can be adjusted to ACL biomechanics.

METHODS: Mechanical properties of dry and wet silk fibers bundles with different twisting levels were assessed with monoaxial tensile tests, to define type and number of filament bundles needed for the mechanical matching with the natural ACL. ACL model scaffolds were prepared by embedding the selected fibers in a fibroin gel that underwent to directional freeze-drying in order to induce the formation of vertical porous pathways [2]. Scaffolds were seeded with AdMSC p3 cells at 30,000 cells/cm² and cultured in static and perfusion chamber conditions. Cell adhesion, proliferation and gene expression tests were performed at different time points (1-3-7-14-28 days) and results were evaluated with biochemical assays, confocal microscopy and qPCR.

RESULTS & DISCUSSION: At increasing twisting levels, the stiffness of the investigated silk fiber bundles increased. Stiffness and load at break of the selected silk bundles are compared in table 1 with those of an ACL. The results indicate that about 30 bundles would be required to fabricate a scaffold with stiffness and strength comparable to those of a natural ACL. Biological tests showed that cells, seeded on the surface, are able to penetrate inside the porous fibroin sponge and also in between the fibers of the bundle, assuming an elongated orientation that is typical of native ACL.

CONCLUSIONS: We demonstrated that using silk twisted fibres, it is possible to fabricate model ligament prostheses with mechanical properties comparable with the natural ACL. Moreover, the use as a matrix of a properly morphological designed fibroin sponge with vertical pores could allow cell penetration and orientation.

INTRODUCTION: Skeletal muscle and bone tissue engineering have great potential to be used to improve repair or to replace damaged tissue [1]. Also, tissue engineering allows to fabricate study models for myopathies and other tissue related diseases. Herein, we have fabricated two polymeric scaffolds that mimic the in vivo tissue and were used to evaluate muscle and bone cell growth. The scaffolds would be probed in a bioreactor with mechanical stimulation.

METHODS: We fabricated poly-ε-caprolactone (PCL) microfilaments for muscle tissue and dental LT resin from FormLabs ® was used for bone scaffolds, through stereolithography (SLA), and sterilized by 25 kGy gamma radiation. To fabricate bone scaffolds we take microCT images to model and imitate the structure of trabecular bone. C2C12 and Saos-2 cell lines were seeded at 50 000 cells/cm², for each 1 mm scaffold height. We evaluate mechanical properties of materials, cell adhesion and viability of muscle and bone cells, for 3, 7, 11 days.

RESULTS & DISCUSSION: Mechanical characteristics were obtained for the polymeric scaffolds, Young modulus was 347.25 ± 30.10 MPa for bone-like structure and 80.02 ± 23.14 MPa for microfilaments. Also, we have found that cells can adhere and grow in both scaffolds, however, cells do not penetrate deep in bone scaffolds, therefore, we need to improve cell seeding. Nevertheless, we note some cell growth on scaffolds edge.

CONCLUSIONS: Scaffolds that simulate muscle tissue and trabecular bone were fabricated. Cells adhere in both biomaterials, however, for bone scaffolds it’s necessary to improve seeding conditions to enhance cell adhesion, growing and distribution into the scaffold. This work represents the beginning at TEC to combine cells with biomaterials to improve tissue regeneration for Costa Rican population.

INTRODUCTION: Bone marrow-derived mesenchymal progenitor cells (MPC) are attractive for cartilage-defect regeneration. Unfortunately, MPC unlike articular chondrocytes (AC), undergo hypertrophy during chondrogenic (re-)differentiation and produce transient cartilage in vitro and bone in vivo [1]. During mouse embryonic development, balancing of transcription factors SOX9, RUNX2, RUNX3 and MEF2C is associated with chondrocyte hypertrophy [2]. Surprisingly little is known on regulation of these key fate-determining factors during MPC chondrogenesis versus AC redifferentiation. Aim was to uncover regulation of SOX9, RUNX2, RUNX3 and MEF2C during MPC and AC chondrogenic (re-)differentiation and to identify signaling pathways driving possible misregulation in MPC.

METHODS: Human MPC and human AC were isolated after informed consent, expanded and subjected to chondrogenic conditions for up to 6 weeks. qRT-PCR, Western-Blotting, ALP activity assay and histology were performed weekly during (re-)differentiation and after withdrawal of TGF-β, treatment with antagonists or intermittent PTHrP application.

RESULTS & DISCUSSION: AC had higher SOX9-levels but remained negative for RUNX2 and RUNX3 protein throughout redifferentiation. During MPC chondrogenesis, RUNX2 protein was undetectable while RUNX3 and MEF2C mRNA and protein levels were significantly upregulated together with hypertrophic markers. Reduction of TGF-β and BMP-activity but not WNT- or HH-signaling reduced MPC chondrogenesis. Only PTHrP-pulse and IWP-2 treatment specifically reduced hypertrophy. Hypertrophic RUNX3 was driven by TGF-β and BMP-signaling while MEF2C induction involved BMP- and HH-signaling.

CONCLUSIONS: RUNX2, considered as master regulator of endochondral development, apparently did not drive hypertrophy of human MPC. Reduction of RUNX3 and MEF2C transcription factors to AC levels directly or via manipulation of relevant pathways may be promising for guiding MPC differentiation towards an articular chondrocyte phenotype.

ACKNOWLEDGEMENTS: We thank patients for donation of tissue samples.

INTRODUCTION: Engineered neural tissue (EngNT) made using aligned cellular collagen promotes axonal regeneration across critical sized defects [1]. We present alternative hydrogel materials that are suitable for use in EngNT and may improve its regenerative capacity.

METHODS: Decellularization protocols for a range of tissues were adapted [2-3]. dsDNA and glycosaminoglycan (GAG) contents were quantified, and hydrogels were formed. Mechanical properties were characterized using a rheometer (Anton Paar, Hertford, UK). Viability of Schwann cells (SC) incorporated within gels was assessed using the Cell Titer-Glo assay (Promega, Southampton, UK). SC were seeded at 0.5, 1, 2 and 4 x 10\textsuperscript{6} cells/ml to produce contraction profiles and cellular alignment was visualized via immunofluorescence microscopy.

RESULTS & DISCUSSION: Bone extracellular matrix (ECM, B-ECM) possessed the lowest dsDNA content (27.4 ± 5.3 ng/mg) whilst small intestinal submucosa ECM (SIS-ECM) had the highest (424.4 ± 4.0 ng/mg). Similarly, B-ECM had the lowest GAG content at 1.9 ± 0.8 µg/mg, compared to the highest of 5.6 ± 0.9 µg/mg for SIS-ECM. The B-ECM gel displayed the fastest gelation and exhibited a sigmoidal gelation profile. The liver ECM (L-ECM) gel was the stiffest at 453 ± 9 Pa, whilst the urinary bladder ECM (UBM-ECM) was the softest at 61 ± 8 Pa. SC viability was significantly higher for 6 mg/ml compared to 4 mg/ml gels and was highest for SIS-ECM and lowest for B-ECM. Contraction was dependent on both gel and cell concentrations; higher cell concentrations and lower gel concentrations produced the most contraction. Adequate SC alignment was seen in 4 and 6 mg/ml B-ECM and SIS-ECM gels however, no alignment was observed in L-ECM or UBM-ECM gels.

CONCLUSIONS: Biochemical and mechanical properties affect SC viability. B-ECM and SIS-ECM are further suitable for use in EngNT. Future work will involve co-cultures of neurons to assess axonal regeneration.

INTRODUCTION: Injectable hydrogels via minimally invasive surgery offer benefits to the healthcare system reducing the risk of infection, scar formation and cost of treatment. Degradation of the intervertebral disc (IVD) currently has no preventative treatment. The use of an injectable hydrogel material could support IVD mechanical properties and promote tissue regeneration. We present a hydrogel material based on Laponite® associated poly(N-isopropylacrylamide) co poly(dimethylacrylamide). Previous research from our group has already demonstrated in vivo and in vitro efficacy for cell differentiation, migration and tissue integration for both nucleus pulposus (NPgel) and bone tissues (Bgel) [1-3].

METHODS: Hydrogels were synthesised in accordance with previous research [1-3]. Physical properties of different hydrogel formulations were assessed using rheometry, SEM, DSC and swelling for 7 days in PBS at 37°C. The NPgel formulation has also been characterized using dynamic uniaxial unconfined compression (DMA) and degradation was assessed in water, PBS and DMEM (10% FCS) over >48 weeks at 37°C. Gravimetric, ATR-FTIR and ICP-MS data from the degradation study have been analysed using PCA, PLS and multivariate statistical analysis degradation from the data sets.

RESULTS & DISCUSSION: Using a box-Behnken experimental design, we were able to produce hydrogels with ranging shear moduli G* (600-2800 Pa), gelation temperatures (35-38°C) and swelling characteristics (-10% to -40%). DMA of the NPgel formulation demonstrated complex modulus E* of > ~1800 Pa when first gelled; this increased to > ~5000 Pa following 24 hours in PBS. The degradation study showed distinct changes in the NPgel material behaviour at 37°C in salt-based media (PBS and DMEM) compared with water. FTIR of dried NPgel from the degradation study revealed some subtle alterations over time.

CONCLUSIONS: We have demonstrated the ability to customise the hydrogel physical properties to best suit the needs for the IVD. The shrinkage of NPgel in salt-based media was likely the cause of the increased mechanical properties observed in the DMA (Fig 1). The real-time degradation study is still ongoing; however initial results show subtle changes to the material in physiological media over time (Fig 1).

ACKNOWLEDGEMENTS: We would like to thank Arthritis Research UK grant number 21497 for supporting this research.

INTRODUCTION: The integration of vascular structures and mesenchymal compartments into in vitro cultured tissues is critical to study complex cell interactions [1]. Several works highlighted that muscle disorders including dystrophies show an abnormal cross-talk between muscle fibers, endothelium and fibroblasts, emphasizing how targeting different cell types would be critical to effectively tackle this condition. Despite the incidence of dystrophies and their consequences (e.g. fibrosis), in vitro systems are still far from recapitulating the complexity of skeletal muscle and its degeneration. Based on a previous model [2], we here developed a mesoscale system of the human muscle environment to study the onset of fibrosis.

METHODS: The mesoscale system enabled casting of three non-planar muscle fibers (600 µm diameter, 600 µm interfiber distance) and subsequent addition of fibrin hydrogels embedding endothelial cells (ECs) and fibroblasts derived from healthy or Duchenne (DMD) donors [3]. TGF-β1 treatment was used as positive control to induce a fibrotic environment.

RESULTS & DISCUSSION: We characterized the model in terms of vasculature topological parameters, muscle fiber architecture and expression of endothelial and muscle markers. We demonstrated the induction of muscle-specific endothelial features and the self-organization of an endomysium around muscle fibers. We employed the model to mimic the fibrotic environment of muscle dystrophies, which is characterized by abnormal matrix deposition. The expression of collagen I and fibronectin in tissues containing DMD fibroblasts was higher compared to control and TGF-β1-treated samples (p<0.001). DMD fibroblasts also showed higher expression of α-smooth muscle actin compared to control fibroblasts (p<0.001), which is an additional indication of differentiation towards pathological myofibroblasts.

CONCLUSIONS: Musculoskeletal tissue has a distinctive 3D architecture which is fundamental to promote intercellular crosstalk and maintain tissue functionality. Herein, we exploited our 3D mesoscale model to show that the inclusion of DMD derived fibroblasts is sufficient to increase the expression of fibrosis-associated proteins, highlighting differences that are overlooked by traditional 2D assays.

INTRODUCTION: Tissue Engineering (TE) development is strictly related to changes in materials fabrication technology. Biomaterials design and their properties play a critical role in the success of designed scaffolds for TE. A better understanding and control of the biodegradation process may help in the development of successful TE strategies. Moreover, computational modelling offers an efficient framework to predict and understand the behaviour of biomaterials. This work’s aim is to develop a combined in-vitro/in-silico method to quantify artificial scaffold’s degradation.

METHODS: 3D-printed PolyCaproLactone scaffolds were used for the in-vitro degradation tests. To evaluate the influence of perfusion in the degradation process, a customized bioreactor has been developed (Figure 1). Scaffold degradation was evaluated as weight ratio loss. An in-silico approach was also developed to provide a predictive model of degradation. Polyester hydrolysis was modelled through physiochemical rate equations. The hydrolysis kinetic coefficient is a thermodynamic quantity associated with the probability of molecular scission and can depend on different parameters: pH and temperature were considered constant, at 7.4 and 37°C, respectively.

RESULTS & DISCUSSION: Each polymeric molecule is randomly broken at a given ester group. Thus, the number of carboxylic end groups will increase with degradation time, whilst the number of ester groups decrease. The variation of ester bonds molar concentration was used to estimate the molecular weight variation. It seems that perfused scaffolds degrade faster than static ones, Figure 2. This may be due to the shear stress increasing the probability of bond scissions. So, the reaction rate coefficient depends on the shear, whilst it was considered constant for the static condition.

CONCLUSIONS: Driving the polymers degradation is crucial for TE to let the new-born extracellular matrix gradually replace the polymeric artificial structure. However, tests for scaffolds degradation in physiological conditions require very long experimental times. This combined model permits to predict long term behaviour starting from data retrieved from experiments run at short term.

INTRODUCTION: Dental pulp tissue plays a major role to maintain the biological and physiological vitality of the tooth. It is the only vascularized tissue encapsulated in highly mineralized tissue including dentin and enamel. [1-2] Here we introduce an ex vivo bovine tooth culture model to assess the angiogenic potential of different cell-seeded hydrogels.

METHODS: Bovine teeth were prepared to the same length and canal diameter, and were fixed in 24-well plate by agarose gels. Type I collagen (COL), fibrin gel (FIB) and agarose collagen blends (AG-COL) were optimized at the concentration 0.2% COL, 0.5% FIB and 0.5%AG- 0.2% COL. Human dental pulp stem cells (DPSC) and human primary umbilical vein endothelial cells (HUVEC) were co-cultured at the concentration of 3×10^6 respectively in each hydrogel. Cell-loaded hydrogels were cast directly on to the well plates and into bovine teeth canals. The bovine tooth was static in the well plate during the culture period and only allowed medium to get through from the top of the canal mimicking the natural environment of human dental pulp. After 14 days, the hydrogels were evaluated by two-photon laser scanning microscopy (TLSM). The vascularized structures were visualized using anti-CD31 immunostaining and quantified.

RESULTS & DISCUSSION: TLSM three-dimensional (3D) images showed the formation of vascular-like networks in 0.2% COL, 0.5% FIB and 0.5%AG- 0.2% COL cultured in well plates and in bovine teeth. The lumen structures were detected in the side view of 3D images in all conditions. In the bovine tooth-supported culture model, the root canal limited the contacting area of medium and hydrogel, and the tubular formation was shown only in a certain depth (around 200 µm). The tubular length in bovine tooth model and in culture well was measured and compared. The statistical results did not reveal any significant difference (P > 0.05).

CONCLUSIONS: The results demonstrate that the bovine tooth model allows angiogenesis and can be further developed to assess the regenerative potential of different cell-loaded hydrogels ex vivo mimicking the natural dental environment.

INTRODUCTION: To repair soft tissue, it is vital to ensure that the biomaterial is able to mimic the
complex elasticity of the native tissue. Substrate stiffness has a huge influence on cell physiology and
behavior [1,2]. The present study presents a set of polymeric films as initial support matrix of cells.

METHODS: Six (6) resorbable polyesters made from different combination of monomers, such as
lactic acid, glycolic acid, trimethylene carbonate, dioxanone & β-caprolactone, were selected for their
physico-chemical intrinsic properties. Even though the selected polymers have similar chemistry they
show different mechanical and degradation properties.
The films were manufactured by compressing moulding using a thermal presser. The mechanical
properties of the films were assessed by tensile test, dynamic mechanical analysis (DMA) and atomic
force microscopy (AFM) in dry and wet conditions. In vitro assays were performed using human
bone marrow mesenchymal stem cells (SC) to assess the proliferation and differentiation potential of
the biodegradable films. It was also performed single cell analysis to assess the substrate influence in
stem cell adhesion.

RESULTS & DISCUSSION: The mechanical properties of the successfully processed films were
analyzed regarding at their macro level by DMA at 37°C in a phosphate buffer bath, with storage
moduli ranging from 0.1 up to 2.6 GPa. Similar ranking of polyester films was confirmed by AFM.
Biological assays with the stem cells showed good cell adhesion, proliferation & viability in all
conditions. Stem cells were able to differentiate into adipogenic, osteogenic, chondrogenic and
tenogenic lineages. But cell morphology and cluster formation were very different from one to
another polymer. The focal adhesion pattern has been analyzed as well.

CONCLUSIONS: The selection of polymers gives us good options to cover a large range of tissue
repair indications, from their mechanical features. The choice of the right polyester should be driven
not only by their mechanical properties and degradation profile, but also by the nature of the tissue to
be repaired and the bio-instructive properties of the polyesters.

INTRODUCTION: A crucial key milestone for the 3D organ bioprinting is the ability to create specific anatomical features, such as complex shape in the 3D space, vasculature and functional inner structures that cannot be achieved from the standard layer-by-layer planar fabrication [1]. Herein, in a proof-of-principle experiment, we demonstrate the versatility of xanthan gum-based medium to generate i) freeform 3D complex hollow structures and ii) perfusable channels, by acting as a sacrificial or permanent support material, respectively.

METHODS: The 3D model of the arterial tree was designed with computer-aided design (CAD) software (SolidWorks) and printed by using the pneumatic dispensing bioplotter (Envisiontec, Germany). The hydrogel ink was a solution of 3.5% (w/v) sodium alginate. Xanthan gum (XG) was obtained from food industry. Methacrylate-modified XG was obtained via epoxide ring-opening reaction of glycidyl methacrylate [2]. For alginate ionic crosslinking, 50 mM of CaCl2 was added to both support baths exposure.

RESULTS & DISCUSSION: XG medium has enabled to generate a self-supported arterial tree construct with high resolution. Also, the well embedded arterial structure in the XG support bath allowed the formation of three asymmetric branched hollow lumens without collapsing or deforming, during the printing process. After removing from the XG bath, the arterial tree construct still maintained its structural integrity, confirming the alginate printed layers were well fused together. The 3D printing of a spiral alginate filament within a XG support material containing methacrylated moieties allowed the further photocrosslink of the support material forming a hydrogel. The subsequent alginate liquefying process, left a well-defined open channel with the printed pattern through the XG-based hydrogel.

CONCLUSIONS: Xanthan gum provides a support material platform for 3D bioprinting technology of functionally complex biological constructs, opening new prospects for biofabrication technologies in tissue engineering and regenerative medicine.

INTRODUCTION: Basic concept of tissue engineering is fabrication of biological substitution to overcome the limited self-healing ability of human body. Especially, mimicking the native extracellular matrix (ECM) has been an issue in tissue engineering. The ECM of skeletal muscle is well known for its anisotropic pattern and micro fibrous structure. To mimic these biophysical cues, many fabrication methods have been used, such as freeze-drying, electrospinning, 3D printing, etc. In this study, we fabricated 3D structure composed of fibrous PCL bundle using 3D printing technology and a blended sacrificial material.

METHODS: To fabricate a fibrous Poly(-caprolactone) (PCL, M_w=45,000 g/mol) bundle, PCL and pluronic F-127 (PF127) were mixed and printed. The printed structures were immersed in the 3rd distilled water to dissolve the PF-127. Conventional printed PCL structure was used as control group. Porcine collagen type I and EDC/NHS solutions were used for collagen coating process for both groups. Scanning electron microscopy (SEM) was used for capturing surface morphology. The myoblasts (C2C12 cells) were seeded onto the scaffolds, and cell bioactivity such as cell proliferation and differentiation were evaluated.

RESULTS & DISCUSSION: In this study, we were able to fabricate micro-fibrous PCL bundle structure by mixing PCL with PF127. Structure composed of micro-scale PCL fibers shows anisotropic aligned morphology compared to conventional PCL structure. Fibrous-bundle PCL group shows enhanced cell proliferation and myotube formation, compared to PCL group.

CONCLUSIONS: Fabricated fibrous structure showed enhanced proliferation of myoblasts, cell alignment, and myotube formation compared to conventional PCL structure. Based on the results, we conclude that fibrous-bundle PCL could be a new strategy for muscle tissue regeneration.

Mechanical regulation of the corneal epithelium
S. Masterton¹, M. Ahearne²
Presenting Author: Sophia Masterton, masterts@tcd.ie
¹Trinity Centre for Bioengineering, Trinity Biomedical Sciences Institute, Trinity College Dublin
²Department of Mechanical and Manufacturing Engineering, Trinity College Dublin, Ireland

INTRODUCTION: Mechanical stress on cells is known to affect their activity [1], however, little is known about its effect on the corneal epithelium. This study examines how material stiffness regulates epithelial cell behaviour using a human telomerase immortalised corneal epithelial cell line (hTCEpi) with the aim of determining optimal conditions for generating new tissue

METHODS: Polydimethylsiloxane (PDMS) substrates with an elastic modulus ranging from 12kPa to 2240kPa were fabricated. Proliferation marker phosphorylated extracellular regulated kinase (pERK) was examined using western blot and gene expression of cytokeratin 3 (CK3) and cytokeratin 14 (CK14) was quantified at day 7. Immunocytochemistry analysis of intermediate filament protein vimentin was examined at day 3.

RESULTS & DISCUSSION: The medium stiffness group displayed the most significant proliferation compared to all other groups. The stiff group expressed CK3 at a significantly higher rate than other groups. CK14 was significantly increased compared to the control in the medium-soft and soft groups (Fig 1 D). Vimentin expression was lowest in the control and soft groups.

CONCLUSIONS: Substrate stiffness has a significant role to play in corneal epithelial cell proliferation, gene expression and intermediate filament formation. CK14 is a corneal stem cell marker [2] and its expression was increased with softer substrates. CK3 is a mature corneal epithelial marker [2] and its expression was significantly decreased in softer substrates. Cells on the softest samples also had less proliferation and intermediate filament formation. This indicates more of a stem cell phenotype with lower proliferative potential for cells grown on softer substrates and a more mature, higher proliferative phenotype for cells grown on stiffer substrates. Results may be used to design a biomaterial for corneal epithelial tissue regeneration.

INTRODUCTION: A novel sequentially gelating smart bioink based on elastin like recombiners (ELRs) has been developed whose thermo-responsive behavior is exploited for the deposition of well controlled fibers under a heated platform.

METHODS: An ELR bioink showing synergistically combination of thermal responsiveness (hydrophobic aggregation), Leu-Zipper domains, for fast setting and silk-like sequences for late stabilization is tested and compared with control recombiners showing partial functionality. Printability as a function of circularity and scaffold stability in excess of aqueous medium is measured, as well as rheological experiments. In vitro tests are also performed using HFF-1 cell line to prove the Biocompatibility of the bioink.

RESULTS & DISCUSSION: Best ink concentration has been optimised (Figure 1). Printed structures exposed to aqueous media show long term stability in comparison to the disaggregation of the Zipper ELR over time and the inability of the Silk sequence to induce a fast gelation into the Silk ELR. Zipper-Silk ELR bioink shows a Newtonian behaviour at low concentrations with very low viscosity, allowing the formation of complex structures by using small-diameter needles while keeping the shear forces constant (Figure 1). In vitro tests further proved adherence and proliferation of cells, supporting the potential of the presented material (Figure 2).

CONCLUSIONS: Results of this work accentuates the great applicability and novelty of printed biomimetic ELRs structures based on a molecularly programme of gelation setting and stabilization. Applications such as micro-organ, or tissue printing are in the scope of future investigations.

Figure 1: Pr calculated value of the printed structures of the ZELR; SELR, and Zipper-Silk for 120, 150, 180, 200, 250 and 300 mg/mL in PBS 1X (left). Viscosity of the ELR bioink upon increasing of a determined shear rate for different concentrations in PBS 1X (right). INTRODUCTION: The worldwide prevalence of bone disorders and conditions such as bone defects either from trauma or congenital disorders is exponentially increasing. Until now, approaches for bone tissue engineering involve seeding mesoderm derived mesenchymal cells on scaffolds followed by their osteogenic differentiation. Although this could mimic the intramembraneous route for bone formation, which is a unique feature of ectoderm derived mesenchymal stem cells; however efficacy of such constructs is yet to be demonstrated in load bearing long bones.

METHODS: 3D bioprinted constructs with mesenchymal stem cells were cultured in (1) Osteogenic differentiation media containing an additional 1 nM T3 along with 10 nM Dexamethasone, 50 mg/mL ascorbic acid, 10 mM β-glycerophosphate, penicillin, streptomycin, 10% FBS for 21 days or (2) first in chondrogenic differentiation media comprising DMEM, Ham’s F12 media, 50 μg/mL ascorbic acid, 10 μg/mL insulin, 10 μg/mL transferrin, and 100 nM hydrocortisone for 21 days, followed by Osteogenic differentiation media +T3 for 14 days.

RESULTS & DISCUSSION: This study explored the 3D bioprinting strategy recapitulating the path of embryonic bone formation which are formed from a pre-figured cartilage template during embryonic stage. 3D bioprinting of silk-gelatin laden with bone marrow stem cells leads to the chondrogenic differentiation of mesenchymal stem cells followed by osteogenic differentiation thus mimicking the conditions in vivo that takes place during embryonic stage. This finding was supported by the temporal changes in gene expression corresponding to early and end stage osteogenic differentiation of the mesenchymal stem cells in the 3D bioprinted construct, closely mimicking the conditions in vivo. Interestingly, upon addition of T3 and following the endochondral ossification route could trigger the parathyroid hormone (PTH), IHH, and Wnt/β-catenin pathways thus resulting in gene and protein expression similar to one that takes place in vivo. Presently, we are following stable incorporation of trans-genes to precisely control differentiation pathways.

CONCLUSIONS: Innovative bioprinting strategy could replicate (1) chondrogenic condensation and hypertrophic cartilaginous template development, (2) involvement of IHH signaling indicative of the development of bony collar by perichondral ossification, (3) involvement of Wnt/β-catenin signaling, (4) involvement of PTH signaling, and (5) synthesis and deposition of bone-specific mineral. Hence this replication of developmental biology within in vitro set up could ultimately lead to better and stable bone formation akin to the one observed in vivo.

ACKNOWLEDGEMENTS: Financial support was received from Department of Biotechnology, India Govt.

INTRODUCTION: The concept of building an interface between substrate surfaces and biomolecules became very attractive for applications in the biomedical field. These interfaces can be used for manufacturing of biosensing platforms, cell culturing [1] and tissue engineering [2]. Specific surface engineering via synthetic polymer brushes can introduce a chemical environment that can promote cell adhesion, proliferation, viability and enhanced extracellular matrix-secretion functions [3].

METHODS: Flat silicon oxide substrates (e.g. glass, silicon wafer) were activated and amino-functionalized via chemical vapor deposition (CVD) of alkoxy silanes. Reversible addition-fragmentation chain transfer (RAFT) polymerization was applied, to generate polymer brush interfaces on these substrates. An activated ester RAFT reagent was bound to the amino-functionalized surface and in a thermal- or light induced grafting-from polymerization, acrylamide polymer brushes were generated. Aminolysis reactions were used to generate thiol end groups onto the brushes and these were further coupled to maleimide (Mal) nitriloacetic acid (NTA) linkers for His-Tag coupling reactions. The substrates were analyzed by water contact angle (WCA), ellipsometry and total internal reflection fluorescence microscopy (TIRFM).

RESULTS & DISCUSSION: After CVD amino-functionalization, the generation of poly-N-acryloylmorpholine (NAM) polymer brushes on flat silicon oxide substrates was accomplished via thermal and light induced RAFT polymerization. WCA (wetting behavior) and ellipsometric layer thickness analysis confirmed the presence of a polymer brush layer of approx. 20 nm. End group modification by the use of aminolysis was confirmed by ellipsometry and resulting thiol groups were labeled with Alexa 647-Mal to confirm their presence in TIRFM. Thiol end groups were linked to a Mal-NTA spacer and coupled to an Alexa 555 labeled bovine serum albumin (BSA) molecules and the bioconjugation was monitored via TIRFM.

CONCLUSIONS: Based on the collected data, it was possible to create a poly-NAM polymer brush biointerface with BSA protein bioconjugated chain ends.

INTRODUCTION: The menisci are semilunar tissues in the knee responsible for load distribution and joint stability. Menisci can fulfill this function due to the unique structure and composition of their extracellular matrix (ECM), which results in anisotropic mechanical properties that exhibit significant tension-compression non-linearity [1,2]. 3D printing allows tuning of the compressive and tensile parameters of scaffolds to replicate the structure of complex biological tissues. The objective of this study was to use 3D printing to fabricate PCL scaffolds which replicate aspects of the internal architecture of menisci in order to mimic the mechanical properties of the native tissue.

METHODS: A 3D Discovery printer (RegenHU, Switzerland) was used to produce polycaprolactone (PCL, Capa, 40kDa) scaffolds. Constructs with spacing between the fibres of 0.25, 1 or 2 mm, with aligned or offset fibre patterns were printed and imaged. Compressive and tensile testing was conducted with a Zwick/Roell material testing machine.

RESULTS & DISCUSSION: The spacing and printing pattern dramatically influenced the compressive and tensile modulus of the scaffolds. A fibre spacing of 0.25 mm and 2 mm resulted in tensile moduli approaching that observed in the circumferential and radial direction of native meniscus [3]. In compression only an offset pattern resulted in a modulus near the native range, independent of the fibre spacing. The pattern therefore affected the compressive modulus without affecting the tensile modulus.

CONCLUSIONS: Using a scaffold architecture of 2 mm spacing and an offset print pattern it is possible to print scaffolds mimicking the compressive and tensile modulus (in radial direction) of the native meniscus. Decreasing the fibre spacing was necessary to match the tensile stiffness in the circumferential direction. Future studies will seek to combine such PCL frames with bioinks to produce functional meniscal implants.

Delayed reconstruction of peripheral nerves by mean of chitosan conduit filled with muscle fibers

S. Raimondo

Nerve fiber regeneration and complete functional recovery after peripheral nerve injury do not always occur and can be influenced by many factors, including time interval that elapses before performing surgical repair. The poor outcome occurring after a long delay can be due to loss of neuron ability to regenerate, loss of Schwann cell ability to support regeneration and the consequent ineffective support for nerve regeneration. One of the most important factors regulating Schwann cell action is Neuregulin1 (NRG1), which is highly up-regulated following acute nerve injury, while it is strongly down-regulated during chronic nerve degeneration. Taken together these data suggest that providing a source of soluble NRG1 might be a good strategy to improve the outcome after delayed nerve repair. In the present study, to provide a three-dimensional environment and trophic factors supporting Schwann cell activity and axon re-growth, we combined the use of an effective conduit (a chitosan made tube) [1] with a promising intraluminal structure (fresh longitudinal skeletal muscle fibers). Fresh skeletal muscle produces and releases high levels of soluble isoforms of NRG1 and for this reason we chose it to enrich hollow chitosan tubes. In particular in this study the efficacy of this enriched tubular device was evaluated as a support of nerve regeneration after a delayed surgical nerve reconstruction (secondary repair). After 3 months of denervation, the median nerve was repaired with autologous nerve grafts (as control) or chitosan tubes filled with a longitudinal piece of pectoralis major muscle (muscle-in-tube). Regenerating nerve samples were harvested 4 months after nerve reconstruction for morphological and stereological analysis. Results showed that the chitosan conduit enriched with muscle fibers is as effective as the autograft, the "gold standard" technique for nerve reconstruction, in promoting nerve regeneration [2].

INTRODUCTION: Macromolecular crowding (MMC) was shown to significantly increase extracellular matrix (ECM) deposition and to promote chondrogenic differentiation of stem cells. Herein, we assess the influence of MMC on chondrogenic differentiation of human adipose derived mesenchymal stem cells (hADSCs) in different 3D culture systems in order to fabricate ECM-rich chondrogenic tissue substitutes for tendon enthesis repair.

METHODS: hADSCs were seeded on Collagen type I and type II sponges, on thermoresponsive electrospun fibres, in order to obtain viable cell sheets, and in pellet culture. Carrageenan (50 μg/ml) was used as MMC agent. Histologic and gene expression analysis were conducted after 7, 14 and 21 days of chondrogenic induction.

RESULTS & DISCUSSION: MMC induced increased ECM deposition and therefore thicker cell sheets could be harvested compared to controls. Alcian blue staining showed increased deposition of sulphated glycosaminoglycans (sGAGs) in collagen type II sponges after 21 days in the presence of carrageenan (Figure 1). In a scaffold-free approach, ADSCs showed the highest chondrogenic differentiation potential compared to all other culture systems after 21 days and viable multilayer cell sheets could be harvested (Figure 1).

CONCLUSIONS: Collectively, these data indicates a beneficial effect of MMC on chondrogenesis in different 3D culture systems with chondrogenic cell sheets as a promising candidate for transplantation into tendon enthesis defects. The fabrication of tissue equivalents can be achieved within very short culture times, preventing phenotypic drift of stem cells.

INTRODUCTION: The use of biomaterials allows to generate active biophysical signals for directing stem cell fate through 3D microscaffolds, such as the one named “Nichoid” [1]. The aim of this study was to investigate: i) the proliferation, differentiation and stemness properties of neural precursor cells (NPCs) [2, 3] following their cultivation in the Nichoid substrate; ii) the therapeutic effect and safety in vivo of NPCs cultivated in the Nichoid in preclinical experimental model of Parkinson’s Disease (PD).

METHODS: Nichoids were fabricated by 2PP onto circular glass coverslips using a home-made SZ2080 photoresist. NPCs were grown inside the Nichoid for 7 days (1x10^4 cells/cm^2), counted and characterized with immunofluorescence, western blot, and Real Time PCR analysis. NPCs were transplanted in a murine experimental model of PD after a 7 days’ growth inside the Nichoid. Parkinsonism was induced by the intraperitoneal administration of MPTP in C57/bl mice (Fig.1) [3].

RESULTS & DISCUSSION: NPCs grown inside the Nichoid create a 3D carpet expanding inside the scaffold. 7 days after plating, cells grown inside the Nichoid show a significantly higher cell viability and proliferation than in normal floating culture conditions. Furthermore, after being replated in floating conditions for 7 more days, the cells formed smaller but more abundant neurospheres respect to control. The replated cells, analyzed by immunofluorescence, Real Time-PCR and Western blot, demonstrate an increase in stemness markers. The therapeutic potential and safety of Nichoid-grown NPCs was evaluated by their intrastriatal infusion (7x10^4 cells) in the brain of PD affected mice. Behavioral performances were evaluated with two different tests showing that Nichoid-grown NPCs promoted the recovery of PD symptoms better than NPCs maintained in normal floating conditions.

CONCLUSIONS: Stem cells demonstrated an increase in stemness potential when grown inside the Nichoid, showing great promise and strong application in the field of regenerative medicine applied to neurodegenerative disease.

INTRODUCTION: The similarity of alginate hydrogels to soft tissue often renders them undetectable with biomedical imaging. In vivo material behaviour is thus poorly understood, posing a challenge to preclinical development and clinical translation. To address this, we demonstrate a new labelling technique for tracking alginate hydrogels using translational, quantitative in vivo imaging techniques SPECT (single photon emission computed tomography) and PET (positron emission tomography).

METHODS: Alginate’s ability to bind metal cations including Ca²⁺ suggested to us that the radiometals ¹¹¹In³⁺ and ⁸⁹Zr⁴⁺ might act as cross-linkers to enable rapid radiolabeling (1a). In and Zr crosslinked alginate hydrogels were synthesized and probed using X-ray Photo-electron Spectroscopy (XPS), and FTIR (Fourier Transform Infrared) to determine metal-alginate binding. Rheometry and scanning electron microscopy probed the effect on visco-elasticity and porosity or hydrogels crosslinked with Ca²⁺ with/without InCl₃ or ZrCl₄ equivalent to 1 GBq/mL. Radiolabelling stability was measured using dialysis. ¹¹¹In-alginate was imaged with SPECT in a model of cardiac tissue engineering.

RESULTS & DISCUSSION: Co-ordination of In³⁺ and Zr⁴⁺ with carboxyl and hydroxyl groups on alginate sugar subunits was demonstrated by FTIR and XPS analysis. Porosity and viscoelasticity of Ca²⁺-crosslinked hydrogels was unchanged at concentrations of In and Zr relevant for clinical imaging with PET and SPECT. Alginate hydrogels were synthesized in sheets, beads, and microbeads using ⁸⁹Zr and ¹¹¹In and imaged with PET and SPECT (1b). In vivo tracking of radiolabelled alginate hydrogels was evaluated in various clinically-relevant applications including cardiac tissue engineering. Co-localisation of viable luciferase-expressing MSCs transplanted in 2% w/v ¹¹¹In-alginate to the cardiac wall was shown over 9 days with in vivo and ex vivo bioluminescence imaging, SPECT-CT, and autoradiography, allowing determination of injection success and retention period.

CONCLUSIONS: Alginate polymers co-ordinate metal cations enabling rapid radiolabeling with ⁸⁹Zr⁴⁺ and ¹¹¹In³⁺ for PET and SPECT imaging. In a cardiac tissue engineering model, cell location and retention period, and injection success or failure could be determined non-invasively. This ability to obtain information on whole-body biodistribution dynamics of alginate hydrogels will facilitate translation of novel therapeutic formulations for drug delivery, cell encapsulation and tissue engineering.

INTRODUCTION: The recurrence rate of chronic osteomyelitis in adults is close to 30% [1]. Bacteria are known to migrate deeper into bone tissue through canaliculi and evade common systemic- and local-antibiotic therapies [2]. By fabricating antibiotic loaded poly(ε-caprolactone) (PCL) microspheres conjugated with the bone-chelator poly(aspartic acid) (PAA) we aim to prolong the microsphere residency near the site of infection, increasing bactericidal potential.

METHODS: Hydrophobic Gentamicin-dioctyl sulfosuccinate (Gen-AOT) loaded PCL microspheres were made by oil/water emulsion methods. In vitro antimicrobial properties were tested by zone of inhibition (ZOI) in a serial plate transfer test with S. aureus. In vivo antimicrobial efficacy of 1 mg of microspheres was tested in a femoral defect in rats (n =5), infected with 2·10⁶ colony forming units (CFU) of bioluminescent Xen-29 a week prior to treatment. In a 2nd study, the PCL microspheres underwent conjugation with PAA by carbodiimide chemistry. Interaction with bone mineral was assessed in the same model as above. IR780 iodide loaded PCL or PCL-PAA microspheres (1 mg) were injected in the bone defect and traced using an in vivo imaging system (IVIS Lumina III, Perkin Elmer).

RESULTS & DISCUSSION: ZOI of Gen-AOT loaded PCL was measurable for 5 days, while a ZOI for bactericidal collagen-sheets was visible for 3 days. The Gen-AOT loaded PCL microspheres caused an 81% reduction in CFU compared to untreated control. In vivo, a brighter signal was measured for PCL-PAA compared to PCL microspheres, validating the hypothesis that PAA-grafted PCL resides longer in bone as control PCL.

CONCLUSIONS: In the presented animal model, a monotreatment of 1 mg PCL microspheres caused an 81% CFU reduction. PCL-PAA microspheres enhance bone affinity by chelation of the PAA to bone mineral at the femoral defect. Further work is required to optimize the bone-targeted drug delivery system to bone.

INTRODUCTION: Diabetes is a chronic, incurable disorder characterized by lack of resistance to insulin leading to an excess of sugar in the blood controlling the oral epithelium homeostasis [1,2]. Alterations or disruptions of the epithelium integrity can ultimately result in chronic inflammation, and tooth loss.

METHODS: We engineered a 3D disease-like organ on a chip system to deconvolute the dynamic contribution of epithelium in diabetic periodontitis. The in-vitro disease epithelium model is a microfluidic platform that is comprised of 3D cylindrical channel (diameter 160 µm) embedded with collagen I. Human oral keratinocytes (HOKs) were seeded and allowed to adhere through the collagen wall.

RESULTS & DISCUSSION: The epi-oral tube was exposed in 11 nmol/ml of glucose to mimic diabetic epithelium. In addition, we introduced a pro-inflammatory stimulus into the chip, named lipopolysaccharides (LPS) (100 ng/ml) for 1hr. The diffusion of fluorescent dextran (70 kDa Texas Red, Thermo Fisher) (12.5 μg/mL) was imaged in real time with a confocal microscope (LSM 800, Carl Zeiss). The diffusive permeability coefficient (Pd) was calculated by measuring the flux of dextran into the collagen gel and fitting the resulting diffusion profiles to a dynamic mass conservation equation as described previously [3]. The Pd was increased dramatically in LPS treated diabetic conditions compared to non-diabetic ones. Finally, LPS treatment increases FOXO1 translocation in diabetic HOKs.

CONCLUSIONS: Collectively, the 3D epi-oral model substantial provides insights on periodontitis area by developing sophisticated approaches, based on the tissue-on-a-chip technology, avoiding the limitations of the 2D standard cell culture and enabling us to approach FOXO1 mechanisms in a more detailed manner.

INTRODUCTION: Screening tumor biopsies from cancer patients and estimation of the drug combinations to be administered has been a challenge [1], [2]. Hence, we have developed a microfluidic platform with strategically placed U-shaped wells for screening the combinatorial effect of drugs on tumor spheroids. The system enables to study the individual effect of 3 drugs (Paclitaxel(P), Vinorelbine(V) and Etoposide(E)) and the combination (P+V, P+E, V+E, P+V+E) of drugs on tumor spheroids (A549 cell line).

METHOD: The platform allows self-formation of tumor spheroids on passing the cancer cells through the inlet port. We have compared the effect of drugs on the spheroids in chip with the effect of drugs on spheroids in static culture in a 96-well plate. We performed live/dead assay, MTT assay and picogreen assay to determine the cell viability in the tumor spheroids in presence of drugs. Cryo-sections of the drug treated spheroids were stained with hematoxylin and eosin to study the necrosis/apoptosis of cells within the 3D spheroid.

RESULTS & DISCUSSION: The combined effect of all three drugs (Paclitaxel- 10 nM, Vinorelbine- 10nM, Etoposide- 25nM) showed an IC50 at 72 hours which was much lower than the effect of drugs individually or as pairs. The design of the chip is shown in Figure 1.

CONCLUSIONS: A rapid, cost-effective and patient specific microfluidic system has been developed for identifying the exact combination and concentration of drugs required for individual treatment. This would be an invaluable step for developing a personalized healthcare set-up for cancer diagnostics and treatment.

INTRODUCTION: Following injury, cardiovascular disease may arise from inefficient cardioprotection, defective repair and lack of myocardial renewal. We reported that human amniotic fluid stem cells (hAFS) are cardioprotective on rodent ischemic myocardium and on cardiac cells exposed to cardiotoxicity. Here we analyze the hAFS secretome potential to: i) enhance cardiac repair and ii) trigger endogenous regenerative mechanisms.

METHODS: c-KIT+ hAFS were isolated from leftover samples of II trimester amniotic fluid for prenatal screening and stimulated under 1% O$_2$ to enrich their conditioned medium (hAFS-CM) with paracrine factors. Paracrine anti-apoptotic, angiogenic, and proliferative effects were evaluated on rodent neonatal cardiomyocytes (NVCM), human endothelial colony forming cells (hECFC) and human epicardial progenitors (hEPDC). A preclinical mouse model of myocardial infarction (MI) was treated with a single intra-myocardial injection of: total hAFS-CM; conditioned medium depleted of extracellular vesicles (hAFS-DM), and hAFS-extracellular vesicles (hAFS-EV).

RESULTS & DISCUSSION: hAFS-CM improved survival of NVCM undergoing oxidative and hypoxic damage; it induced Ca$^{2+}$-dependent angiogenesis in hECFC and triggered hEPDC and NVCM proliferation. In contrast to hAFS-DM, hAFS-CM enriched with EV counteracted scarring, supported cardiac function and triggered cardiomyocyte cell cycle progression (p<0.05). hAFS-CM also induced reactivation of endogenous EPDC, similarly to hAFS-EV (p>0.05). Although no EPDC cardiovascular differentiation was observed, our data suggest paracrine contribution to local angiogenesis. Transfer of hAFS-EV microRNA into myocardial tissue following MI might explain the increase in resident cardiomyocyte cell-cycle progression.

CONCLUSIONS: From our data the secretome soluble component (hAFS-CM and hAFS-DM) is more likely to drive therapeutic angiogenesis, while hAFS-EV improved cardiac function and triggered EPD cell cycle re-entry. Thus, the hAFS secretome fractions may be relevant for cardiac regenerative medicine.

INTRODUCTION: Clinically anti-adhesive therapies are mostly based on hyaluronic acid-based membranes, but it is expensive, incomplete coverage, and uncontrollable mechanical property and gelation time for different patient. Since each patient’s the severe degree of tissue adhesion is different, it is necessary to prepare an anti-adhesive hydrogel that can meet various needs, such as high mechanical strength, flexible, low immune response and durable anti-adhesion.

METHODS: Serum from the rabbit blood, and serum-based conjugate are modified with tyramine or 2-Aminoethyl methacrylate hydrochloride (AEMA). 80 ul of albumin-Ph conjugated, 50 ul of albumin-AEMA conjugated and 10 % of photoinitiator were mixed to form 5 % albumin-based hydrogels. The 1st step of chemical crosslinking is carried out by adding 10 μl HRP and 10 μl H2O2. The 2nd step of photocrosslinked is formed by irradiation with UV.

RESULTS & DISCUSSION: In this study, we developed an adjustable, biocompatible, customized and two-stage cross-linked serum hydrogel through different chemical modification with functional groups. The serum hydrogel shows controllable gelation time, mechanical properties, proteolytic crosslinking. A mouse model of sidewall defect-bowel abrasion was employed, and a significant reduction of post-operative peritoneal adhesion has been found (fig1). It is easy to use and potentially promising for adhesion prevention and drug release for clinical therapy.

CONCLUSIONS: By extracting autologous blood, we have customized a two-stage anti-adhesive material that can release the drug slowly, and can adjust the properties of the material according to the needs of the patient.

INTRODUCTION: The main reason for sever visual impairment following an endothelial trauma is the limited proliferative capacity of human corneal endothelial cells (HCECs). To date, corneal transplantation has been the only therapeutic choice for corneal failures, yet the global donor shortage makes limitation for this therapy (1). Tissue engineering strategies can be promising to compensate for this limitation and production of HCEC grafts (2). The purpose of this study was to produce a transplantable corneal endothelial cell grafts by culturing the human corneal endothelial cells on a membrane made of Nano-chitosan (NCh)-polycaprolactone (PCL) as a transparent carrier.

METHODS: Chitosan nanoparticles were prepared using ionic-gelation method. NCh solution were added to PCL solution to achieve the final ratio of 3:1 (3). Biomechanical features of the membrane were examined after its preparation. HCECs were isolated and cultured on the NCh-PCL membrane. The culture medium contained 5µm Y-27632 and 5 µm Cycloastragenol (CAG) for induction of cells proliferation. The cells phenotype was evaluated by immunostaining against ZO-1, Na+/K+ ATPase. Proliferative activity was examined using MTT assay and related genes expression was analyzed.

RESULTS & DISCUSSION: Replacing of the chitosan with nanochitosan in the NCh-PCL membranes was found to be appropriate scaffold, for its desired biomechanical and safety characteristics as well as improving cell behaviors such as cell adhesion and expansion. Immunostaining against ZO-1, Na+/K+ ATPase and actin filaments showed that treatment with Y-27632 and Cycloastragenol not only promoted the cells adhesion and proliferative activity of the endothelial cells but also maintained the cells shape and phenotype while the irregular cell shapes was obtained in the control cultured HCECs. Investigation of gene expression showed that expression of ZO-1, Na+/K+ ATPase, and HTERT remarkably affected by culturing HCECs on NCh-PCL membrane and treating with Y-27632 and CAG with compared to control.

CONCLUSIONS: NCh-PCL membrane has favored effects on cultured HCECs behaviors such as cell adhesion and proliferation, so, it can be used as a suitable carrier for corneal endothelial cells transplantation. Y-27632 and CAG have synergistic effect on the HCECs phenotype.

High-performance iPS-derived hepatocytes by fabricating 3D culture
T. Akama, F. Tao, N. Kojima

Department of Life and Environmental System Science, Graduate School of Nanobioscience, Yokohama City University, Japan

INTRODUCTION: For drug screening and for toxicity assays, human hepatocytes are indispensable even combined with or without animal models because metabolic characters in hepatocytes are different between human and other animals’ derivation. Therefore, primary human hepatocytes are widely accepted although they cost with metabolic variations among lots, which are hard to maintain for long time in vitro. Differentiation of hepatocytes from iPS cells has a possibility to solve those issues, however, produced hepatocytes have quite less metabolic activity. Meanwhile 3D culture is applicable for the purpose of increasing cellular functions. We have a unique technique to fabricate 3D by using high dose of methylcellulose (MC) [1]. By combining our 3D fabrication with long term culture, we aimed to increase hepatic function in iPS-derived cells.

METHODS: iPS-derived hepatocytes supplied from Reprocell were tested cell aggregation approached by drop culture, V-bottom multiwell, and our unique methylcellulose method. Methylcellulose was dissolved in ReproHepato culture medium to be 3%, then injected 1 µl suspended 2k cells, followed by releasing obtained spheroids with cellulase and transferring into ultra-low attachment surface culture wells. Progression of cell aggregation was observed over time. After culture, RNA was harvested to evaluate hepatic function by measuring CYP3A4 gene expression.

RESULTS & DISCUSSION: Among cell aggregation methods, drop culture could not aggregate to the end, 48 hours later. V-bottom wells gradually fabricated cell spheroids over 24 hours. Meanwhile, 3% MC medium quickly aggregated cells within 30 minutes after injecting cell suspension, then firm spheroids were fabricated even after releasing from MC medium. Fabricated spheroids were cultured for 6 and 14 days together with monolayer 2D culture control. Then harvested RNA was analyzed gene expression, demonstrated 3D culture did not have remarkable different expression with 2D control after 6 days culture. However, after 14 days culture, CYP3A4 gene was induced drastically. The trend of gene induction was shown by all of multiple cell lots with upregulation range between 30 to 300 times.

CONCLUSIONS: Taken together, we succeeded in establishing more functional hepatocytes without gene modifications or inducible drug treatments. Our method will lead to more physiological liver function assays in vitro not depending on human liver primary.

ACKNOWLEDGEMENTS: This research was supported by Japan Agency for Medical Research and Development (AMED).

Engineering prevascularized tissue engineered constructs by harnessing the leaf vasculature on natural-origin multilayered membranes
T. Pesqueira¹, J. Borges¹, J.F. Mano¹

Presenting Author: Tamagno Pesqueira, tamagno@ua.pt
¹Department of Chemistry, CICECO – Aveiro Institute of Materials, University of Aveiro, Campus Universitário de Santiago, 3810-193 Aveiro, Portugal

INTRODUCTION: Despite significant research efforts to date, the lack of vascularization in tissue engineered constructs remains one of the major challenges in tissue engineering and regenerative medicine (TERM) strategies. The inefficiency of nutrient and oxygen delivery within highly intricate structures hinders their scale-up and translation into clinical setups. Plant leaves’ microvascular network greatly resembles the human circulatory system representing a promising platform to create pre-vascularized tissues. Layer-by-Layer (LbL) is a simple technology for the build-up of highly ordered and organized nanosized-based multilayered structures on top of any substrate by resorting to a plethora of building blocks exhibiting complementary intermolecular interactions. This versatility allows the development of prevascularized platforms which present great relevance in TERM strategies and own great potential for clinical translation.

METHODS: Innate leaf vasculature was replicated in a PDMS mold, later used as substrate for LbL assembly of chitosan (Sigma-Aldrich) and alginate (Sigma-Aldrich) biopolymers into free-standing multilayered membranes. Fibronectin (20 µg/mL, Sigma-Aldrich) was immobilized on their surface via EDC/NHS coupling chemistry. Human umbilical vein endothelial cells (HUVECs) were cultured with endothelial cell culture medium (M199, Sigma -Aldrich) and seeded at 25,000 cells/cm² on top of the membranes up to 21 days. At specific time-points, cell viability, DNA quantification, and nuclei and cytoskeleton fluorescent staining were performed. Non-vascularized membranes were used as control.

RESULTS & DISCUSSION: HUVECs remained viable and proliferated over time when cultured on both control and vascularized membranes. However, the cell migration towards the vascular network pattern and its density was significantly enhanced on the vascular network, as observed by fluorescence and brightfield microscopy.

CONCLUSIONS: HUVECs not only migrated towards the vascular network but also along the network leading to the development of de novo blood vessels. The cell migration was assessed by fluorescence microscopy and confocal laser scanning microscopy (CLSM). The cells were stained with non-toxic cell membrane tracers for real-time monitoring. The evaluation of microcapillary tube formation was performed by flow cytometry (e.g. CD31, CD144, VEGF). CLSM was also used to assess protein expression (e.g. collagen type I, CD31, vWF). Microscopy techniques enabled the visualization of the vascular network pattern and assessment of endothelial cell lumen and tube formation. Collectively, we foresee the development of synthetic blood vessels with promising clinical applicability as patches and cell sheets or as a model for cell co-culture and cell crosstalk studies.

¹Department of Biomedical Engineering, Technion Israel Institute of Technology, Israel

INTRODUCTION: The main goal of our study is to establish a high-throughput growth model system that will be used as an in-vitro drug testing, diagnostics, and cell characterization tool. First, an optimal PEG-Fibrinogen (PF) hydrogel composition for cancer cells outgrowth from cell-line based tumors as well as from human biopsies was established. Our current efforts are focused on validating the established conditions and implementing them in a design of a unique high-throughput microfluidic device.

METHODS: "Artificial tumors" were made by encapsulating a co-culture of the malignant MDA-MB-231 cells and fibroblasts in PF precursor hydrogels, followed by UV-light crosslinking [Fig.1A]. Next, to promote cancer cell outgrowth from human biopsies, the hydrogel composition was altered in various strategies, including the alteration of matrix stiffness and fibrinogen concentration, as well as added fibronectin, Laminin-511, or fibroblast cells into the hydrogel matrix. Finally, a PDMS microfluidic device was designed [Fig.1B] to implement the hydrogel system for high-throughput production of hydrogel μspheres.

RESULTS & DISCUSSION: Preferential cancer cell outgrowth was validated using cells that express fluorescent proteins, eliminating any unspecific migration of fibroblast or EMT/MAT effects that can alter future drug screening results. Next, explants from different types of human primary tumors were retrieved from liver metastases and were encapsulated using the conditions proven successful for the artificial tumors. Various strategies were employed to enhance the cancer cell outgrowth from the biopsies. Among them were alterations of matrix stiffness, incorporation of Fibronectin or Laminin-511. Whereas most conditions failed to promote cancer cell invasion, namely a higher matrix stiffness together with a lower Fibrinogen concentration did lead to cancer cell invasion. Finally, we designed a high-throughput microfluidic device to enable us to produce many highly homogeneous tumor hydrogel μspheres without or with MDA-MB-231 cancer cells.

CONCLUSIONS: The objective of our study is to engineer a high-throughput device that will enable us to produce highly homogeneous tumor hydrogel μspheres from dissociated cells isolated from relatively small tumor biopsy samples. Consequently, we will be able to examine the motility and outgrowth parameters of the cells invading the surrounding hydrogel milieu. Moreover, the device could be implemented as an in-vitro drug testing and diagnostics tool.
Innovative bone substitute to prevent device-associated infections

T. Padrão 1,2,3, C. C. Coelho1,2,4,5, P. Costa6, P. A. Quadros5, S. R. Sousa1,2,3, F. J. Monteiro1,2,4

**INTRODUCTION:** Among the most challenging problems in bone surgery are device-associated infections. This type of infections causes major morbidity, an enormous financial burden to the healthcare systems and a lot of suffering to the patients [1]. Therefore, it is mandatory to develop bone substitutes with antibacterial properties to prevent them. In addition, for the commercial success of these products, several features must be taken into account such as shelf-life and handling properties [2, 3]. For this purpose, a granular bone substitute was produced, combining the biological properties of hydroxyapatite (HAp) together with the antibacterial activity conferred by magnesium oxide (MgO).

**METHODS:** The granules were produced as described [3] using two sintering temperatures and its effect on morphology, phase composition, surface charge and mechanical strength were evaluated. In addition, their antibacterial effect was studied towards S. epidermidis, one of the major pathogens associated to implanted medical device infections.

**RESULTS & DISCUSSION:** XRD results showed that the inclusion of MgO did not induce changes in calcium phosphate phases. However, there was a change in the zeta potential of these materials. SEM images revealed a different surface topography in terms of HAp grain size. The results of compression strength showed that higher sintering temperature also resulted in granules with increased mechanical strength, as expected. These differences also influenced the antibacterial activity, as granules sintered at higher temperature presented a decreased antibacterial effect.

**CONCLUSIONS:** Both HAp/MgO granules sintered at two temperatures were able to significantly reduce S. epidermidis growth, in comparison with pure HAp materials.

**ACKNOWLEDGEMENTS:** This work was financed by FEDER funds through the COMPETE 2020–POCI, Portugal 2020, Portuguese funds through FCT/MCTES in the framework of the project “Institute for Research and Innovation in Health Sciences (POCI- 01-0145-FEDER-007274) by projects Biotherapies (NORTE-01-0145FEDER-000012) and NoMic2Bone (NORTE-01-0247-FEDER-017905). The provision of HAp by FLUIDINOVA, S.A. (Portugal) is acknowledged.

INTRODUCTION: Corneal blindness is the third most common cause of blindness worldwide, disproportionately impacting populations in the global south. Corneal disease generally involves damage to the limbal area which results in cells invading and occluding the normally clear cornea and leads to reduced vision or blindness. A successful surgical technique, called SLET (Simple Limbal Epithelial Transplantation), uses an explant limbus of healthy cornea stem cells which are held in place using human amniotic membrane. This technique relies on the availability of tissue banks for amniotic membrane, which are far less common in the global south and has the risk of disease transition and problematic supply chain. Our group has previously produced synthetic electrospun membranes in collaboration with India to be used as artificial replacements for the amniotic membrane. Previous work in India has resulted in human trials using these membranes but surgeons found the membranes were too stiff and brittle to handle easily. The aim of this project is to produce membranes with a lower Young’s modulus than previous membranes while keeping all other properties as similar as possible.

METHODS: Plasticisers PCL, PEG400 and glycerol were added to PLGA 50/50 for electrospinning into membranes. Resulting membranes underwent mechanical testing to determine their Young’s modules and DLC to determine their glass transition temperature. Membranes were stored at -20°C for 6 weeks and then re-tested to determine any impact from storage. Accelerated degradation studies were carried out to ensure membranes would degrade within 8 weeks once implanted. Cell viability with human cornea cells and porcine cornea models was investigated to test membrane toxicity using MTT and PrestoBlue metabolic assays. Confocal microscopy was used to image cell morphology on the membranes using DAPI and FITC phalloidin.

RESULTS & DISCUSSION: The addition of plasticisers altered the mechanical properties of the membranes, reducing the Youngs modulus and the glass transition temperature. The morphology of the fibres was also impacted by the plasticisers. Degradation tests showed that scaffolds degraded within the 8 week window required for the operation parameters. No significant toxicity was observed with the addition of the plasticisers.

CONCLUSIONS: Membranes for cornea SLET have been manufactured with a lower Young’s modulus while maintaining the previous desired properties. Plasticisers have long been used to influence the mechanical properties of plastics and their use in low dosages has had little impact on the other properties of the membranes. This project will allow the production of membranes which are more suitable for human use and will potential remove the requirement for amniotic membrane in SLET surgery.

INTRODUCTION: The seeding of scaffolds with the stromal vascular fraction (SVF) of adipose tissue is a common prevascularization strategy. We herein demonstrate benefits of using the novel approach of scaffold prevascularization with adipose tissue-derived microvascular fragments (ad-MVF).

METHODS: SVF single cells and ad-MVF were enzymatically isolated from epididymal fat pads of green fluorescent protein (GFP)+ donor mice to assess their viability, activity and cellular composition using fluorescence microscopy and flow cytometry. Additionally, collagen-glycosaminoglycan matrices (Integra®) were seeded with identical amounts of the isolates and implanted into full-thickness skin defects within dorsal skinfold chambers of GFP-recipient mice for intravital fluorescent microscopic, histological and immunohistochemical analysis of scaffold vascularization and incorporation throughout an observation period of 2 weeks.

RESULTS & DISCUSSION: While both isolates contained a comparable fraction of endothelial cells, perivascular cells, adipocytes and stem cells, ad-MVF exhibited a significantly higher viability. After in vivo implantation, the vascularization of ad-MVF-seeded scaffolds was improved when compared to SVF-seeded ones, as indicated by a significantly higher functional microvessel density. This was associated with an enhanced cellular infiltration, collagen content and density of CD31+/GFP+ microvessels particularly in the center of the implants. In contrast, non-seeded matrices exhibited a rather poor vascularization, incorporation and epithelialization over time.

CONCLUSIONS: The present study demonstrates that ad-MVF are highly potent vascularization units that markedly accelerate and improve scaffold vascularization when compared to the SVF.

Figure 1: Intravital fluorescence microscopy of implanted, SVF-seeded (a) and ad-MVF-seeded (b) scaffolds on day 14 after implantation into dorsal skinfold chambers of C57BL/6 recipient mice (dotted lines = scaffold borders; asterisks = center zones; scale bars = 500 µm). Note that newly formed blood vessels did not reach the center zones of SVF-seeded scaffolds whereas ad-MVF induced a strong vascularization throughout the entire scaffolds.

INTRODUCTION: Multiscale modelling has gained importance in simulating different levels of
organs [1]. Defining influence of biomaterial presence to cell growth and cell proliferation is a topic
of wide research, as well as immune response to biomaterials [2], in order to define level of
biomaterial compatibility with innate immune cells and to see if the biomaterial presence induces
adverse immune reactions. We aim to develop a granuloma-on-a-chip system for risk assessment of
new biomaterials by i) finding the right cytokine conditions for granuloma induction ii) simulating
the behavior of monocytes for optimal physiological attachment to biomaterial surfaces.

METHODS: Simulations of bioreactor on macro scale would mean examining behavior of the fluid
flow, monocytes distribution, attachment etc. [3]. We first analyzed fluid flow within the reactor with
monocyte cells. Geometry of the bioreactor was based on the dimensions obtained from literature.
Prescribed boundary conditions included inlet velocity (4mm/s) and zero pressure at the outlet.
Monocytes were introduced with the fluid at the inlet. Model was analyzed using two commercial
software - ANSYS and COMSOL, as well as open solver PAK, developed at the University of
Kragujevac and BioIRC. Navier-Stokes equation together with the continuity equation were used to
model fluid inside bioreactor, and movement of monocytes was modelled as mass transport through
the fluid. Trajectories of the monocytes were obtained based on calculated drag force.

RESULTS & DISCUSSION: Presented model of bioreactor was used for simulation of tracking the
monocyte cells inside the bioreactor. Obtained results from different solvers – ANSYS, COMSOL
and PAK, show good agreement with each other and with experimentally obtained results.

CONCLUSIONS: The presented model of fluid flow through bioreactor and monocyte trajectories
sets good basis for further analysis of monocyte behavior. Future models will include equations for
monocyte deposition within the bioreactor, which would simulate inflammatory process.

INTRODUCTION: The cell-mediated immune response to biomaterials is an important research field in the development of new materials for medical applications. Especially macrophages play a significant role in the defense against foreign bodies and the formation of fibrous capsules. To prevent such an undesired pro-inflammatory reaction, e.g. upon implantation of a biomaterial, different approaches can be used. In our study, we used the novel technology of melt-electrowriting (MEW) to produce 3-dimensional polycaprolactone (PCL) scaffolds with a porous topography, which influence the spontaneous in vitro-polarization of human macrophages into the anti-inflammatory, regenerative M2-type.

METHODS: Human monocyte-derived macrophages were cultivated for seven days on PCL scaffolds with square-shaped pores of 40, 50, 60, 80 and 100 µm in side length. A 2-dimensional (2D) PCL film was used as a control. To detect their spontaneous polarization, cell culture medium without differentiation factors was used. After seven days, the differentiation was analyzed on gene expression, cytokine release and phagocytic activity.

RESULTS & DISCUSSION: Significant (p < 0.05) upregulation of M2 markers (e.g. CD163) and downregulation of M1 markers (e.g. IL-1b) at the gene expression level were observed for macrophages cultivated on scaffolds with the smallest pore size (40 µm) compared to scaffolds with bigger pore sizes and to the 2D-PCL control. Furthermore, the release of the anti-inflammatory cytokine IL-10 was significantly higher for macrophages cultivated on scaffolds with a pore size of 40 µm. Additionally, the investigation of the phagocytic activity showed a pore size-dependent effect: With increasing pore size of the scaffolds, the macrophages increased the uptake of 2 µm latex beads.

CONCLUSIONS: We have proven that especially macrophages cultivated on scaffolds with 40 µm pore size upregulate typical anti-inflammatory macrophage markers without the need for additional stimulating chemicals. Hence, the production of MEW-derived 3D PCL scaffolds with this pore size and the resulting topography might provide a promising tool for medical applications to avoid the undesired pro-inflammatory immune response and to support tissue regeneration.

Figure 1: Macrophages cultivated on MEW-derived PCL Scaffolds with a pore size of 40 µm.

A sound-induced technology for multiscale organization of perfusable micro-vessels networks
Presenting Author: Tiziano Serra, tiziano.serra@aofoundation.org
AO Research Institute Davos, Switzerland

INTRODUCTION: Cell patterns are important for studying morphogenesis, unravelling biophysical mechanisms, and in the development of novel tissue engineering approaches. Surface acoustic wave (SAW) technologies, based on Faraday wave principle, enable the generation of spatially orchestrated particulate systems (cells, spheroids, inorganic aggregates). Patterns shape can be tuned on demand by varying a set of parameters, such as sound frequency, amplitude, chamber shape. Here we propose the use of a SAW-based technology, named 3D sound induced morphogenesis (3D-SIM), which makes possible the generation of precise and reproducible patterns of particulates systems such as cells, spheroids, bioactive particles. We will use 3D-SIM to create precise and reproducible microvascular networks formed by interconnected and perfusable vessels.

METHODS: Primary human mesenchymal stem cells (hMSCs) and human umbilical vein endothelial cells (HUVECs) were used to create complex 3D cell structures. Also, patterns composed by calcium phosphate particles (three different sizes: 32-75 µm, 125-250 µm and 250-500 µm) were tested. As hydrogels: i) gelatin methacryloyl (GelMA, 5%w/v) / Irgacure 2959 solution in PBS and ii) fibrin gel (fibrinogen-thrombin, SIGMA) were used. Finite element analysis (FEA), particle dynamics simulation, was conducted to properly select cell pattern shapes. Morphological analysis via optical and confocal microscope has been carried out. Spheroids formed by HUVECs and hMSCs are patterned in few seconds within an extracellular matrix-like hydrogel. Then, HUVECs sprouting from the patterned spheroids and self-organization into micro-vessels will do the rest.

RESULTS & DISCUSSION: We show that acoustic waves can move cells/particulates systems dispersed in a fluid over an area of 28 cm² in less than 15s. The process is applicable to a wide range of off-the-shelf gelling biomaterial matrices. Layers composed by several combinations of hydrogel and cells/bioactive particles were generated and employed as matrices. Spheroids patterns morphology confirmed FEA investigation. 3D constructs were created by staking layers of patterned cells embedded in hydrogel matrices. Biological evaluation confirmed that 3D-SIM is a mild fabrication process which does not affect cell viability.

CONCLUSIONS: We demonstrate that 3D-SIM is an affordable and user-friendly technology to create 3D cell models in a time-effective manner, with sufficient spatial complexity, retaining cell viability. Hierarchically shaped vessels with a multiscale organization (meso-micro scale), obtained via 3D-SIM, can be integrated into fluidic chip where perfusion can be performed in a reproducible manner with a controlled flow rate.

INTRODUCTION: Native tissues are characterized by a dynamic nature. Recapitulating such dynamicity in engineered tissues requires spatiotemporal control over their biochemical composition. Here, we pioneered supramolecular desthiobiotin/avidin complexation to enable dynamic functionalization of biomaterials. Desthiobiotin is a non-sulfur containing analog of biotin that also interacts with avidin, but with substantially lower binding affinity than biotin [1]. We hypothesized that combining biotinylated hydrogel with desthiobiotinylated bioactive molecules would enable the spatiotemporal functionalization of biomaterials via in situ desthiobiotin/biotin displacement, which is a novel, facile, and fully cytocompatible material modification strategy.

METHODS: Biotinylated dextran-based (Dex-TA) hydrogel constructs were functionalized with 1µM neutravidin (i.e., avidin analog), 1µM desthiobiotin-FITC (D-FITC) and 1µM biotin-atto565 (B-atto565), and subsequently analyzed using fluorescence recovery after photobleaching (FRAP) and confocal microscopy. Surface plasmon resonance imaging (SPRi) and reporter cells were used to analyze the reversible presentation and bioactivity of desthiobiotinylated BMP7 antibodies and BMP7 growth factors.

RESULTS & DISCUSSION: The reversible and sequential modification of the hydrogel constructs was demonstrated by displacing D-FITC with B-atto565. By tuning the concentration and incubation time of B-atto565, we reproducibly controlled its penetration depth into the hydrogel. An injection-molded bone-shaped 3D construct was spatially modified by controlling the thickness of the biotin-displaced layer. Moreover, competitive supramolecular complexation enabled the temporal presentation of desthiobiotinylated BMP7 antibodies and growth factors, as confirmed using SPRi and reporter cells.

CONCLUSIONS: We have successfully developed and characterized a novel spatiotemporal biomaterial modification strategy based on competitive supramolecular complexation.

INTRODUCTION: The versatility and refinement of biomaterials and tissues engineered for regenerative medicine is growing, as is the need to characterize their properties and host interactions. The topography and mechanical properties of biomaterials are crucial parameters that influence cell adhesion/motility, morphology and mechanics as well as the fate of stem and progenitor cells [1, 2, 3].

METHODS: Atomic force microscopy (AFM) is a powerful tool which allows the comprehensive study of all these properties and interactions with nanometer scale resolution under controlled environmental conditions. The inherent drawbacks of traditional AFM imaging modes for fast imaging or for challenging samples like living cells has been impressively overcome by the novel NanoWizard® ULTRA Speed AFM, which not only enables high-speed studies of time-resolved dynamics associated with cellular processes, it’s latest scanner technologies and compact design also allow full integration of AFM into advanced commercially available light microscopy techniques. Thus, fast AFM imaging of several frames per second can be seamlessly combined with methods such as epi-fluorescence, confocal, TIRF, STED microscopy, and many more.

RESULTS & DISCUSSION: Using AFM, mechanical properties like the Young’s modulus of biomaterials, tissues or cells can be determined. Furthermore, the nanostructure of biomaterials like aligned collagen matrices and cell alignment on such structures have been resolved [3]. Using Single Cell Force Spectroscopy (SCFS), cell-substrate or cell-cell/tissue interactions can be measured down to single protein unbinding. The nano-mechanical analysis of cells is increasingly gaining in importance in different fields in cell biology like cancer research and developmental biology.

CONCLUSIONS: We will present how the latest advances in the ULTRA Speed AFM are being applied to study a wide-range of biological specimen, from individual biomolecules to collagen type I fibrillogenesis to mammalian cells and tissues.

INTRODUCTION: Traumatic injuries to the spinal cord lead to a microenvironment where regeneration is poor. Replicating the biomechanics of injury has been shown to be important in understanding the heterogeneity of pathophysiological events [1]. The aim of this work was to investigate the interactions between injury biomechanics and astrocyte responses in a 3D hydrogel model.

METHODS: P2-3 primary Wistar rat astrocyte-seeded collagen gels were prepared at 1x10⁵ cells p.ml⁻¹ of gel [2]. A contusion regime was implemented after 24 hours: contusion (100 or 1000 mm.s⁻¹) to 25, 50, or 75% gel height, 100 ms dwell, and return to 0%. Astrocyte reactivity was measured over a 14-day period using glial fibrillary acidic protein (GFAP) immunostaining.

RESULTS & DISCUSSION: An increase in both displacement depth and velocity resulted in higher loads and thus energy applied to the gel (Table 1). Quantification of the volume of GFAP expression suggests increasing reactivity with increasing displacement, at 100 mm.s⁻¹. Interestingly, at 1000 mm.s⁻¹ a similar level of reactivity was observed across all displacement depths over time.

CONCLUSIONS: Results here suggest an interaction between displacement and velocity, which is in agreement with Lam et al who used a rat SCI model [3]. Between 100 and 1000 mm.s⁻¹ lies a threshold where, below this, injury depth defines astrocyte reactivity. This work has provided the basis for the development of a distraction model. An aligned astrocyte-DRG co-culture model has been developed to investigate the effects of tensile forces on cell behaviour. Increasing the biological complexity and generating an organised cellular architecture aims to bring the model closer to that of the human spinal cord.

INTRODUCTION: Osteogenesis imperfecta (OI) is a heritable disorder of bone matrix formation, usually caused by mutations in the type I collagen genes, COL1A1 and COL1A2, which leads to increased bone fragility, and deformity [1]. It is characterized by poor bone quality, mass, and strength. In this project, we aimed to create a 3D model of extracellular matrix production using electrospun polycaprolactone (PCL) scaffolds [2] to investigate OI effects on in vitro collagen production in order to better understand how type 1 collagen mutations alter early collagen formation processes.

METHODS: PCL pellets were dissolved in dichloromethane, non-aligned and aligned fiber scaffolds were fabricated by electrospinning. Primary fibroblasts and controls were collected from human donors under informed consent from Sheffield’s Children Hospital. For this project, cell-secreted collagen was analyzed using a laser scanning confocal microscope fitted with a Ti: sapphire multiphoton laser. Samples were illuminated and second harmonic generation (SHG) signals were detected.

RESULTS & DISCUSSION: SHG is a powerful imaging tool capable of elucidating collagen structure. SHG has been utilized to assess collagen deposited by fibroblasts in 2D and 3D [3]. As expected, collagen secreted by fibroblasts from healthy donors aligned in the direction of the electrospun PCL fibres of the substrate scaffold (3D). Notably, collagen secreted by OI fibroblasts cultured on aligned fibres produced very low SHG signals suggesting decreased collagen deposition or presence of immature procollagen. Conversely, OI fibroblasts cultured on both non-aligned fibres and tissue culture plastic (2D) produced stronger SHG signals.

CONCLUSIONS: Our results demonstrate that fibrous scaffolds traditionally used for tissue engineering can be used to create in vitro human cell-based, patient-specific models of matrix deposition in 3D. This will be a powerful tool to better understand the mechanisms behind diseases of extracellular matrix production such as OI.

INTRODUCTION: Stem cells are an attractive prospect for regenerative medicine and tissue engineering. However, stem cells are difficult to differentiate into specific cell types. Thus, reliable methods to differentiate stem cells into desired cell types are necessary to be developed. Here, we developed nanosegment-grafted biomaterials having different elasticity. [1] We also developed optimal differentiation media to induce the differentiation of hES cells into cardiomyocytes.

METHODS: We developed several biomaterials having different elasticity for hPSCs differentiation into cardiomyocytes. We prepared (1) ECM (extracellular matrix)-coated dishes, (2) PVA-IA (polyvinylalcohol-co-itaconic acid) hydrogel dishes having different elasticity that are grafted with several ECMs [2], and (3) PVA-IA hydrogel dishes having different elasticity that are grafted with cell-adhesion oligopeptide (oligovitronectin). We also investigated the differentiation efficiency using different induction medium: (a) Commercial cardiomyocyte induction medium, (b) RPMI 1640 medium supplemented with B27 and bovine serum albumin (BSA), (c) CDM3 medium (xeno-free culture medium) developed by literature [3] and in this study.

RESULTS & DISCUSSION: On day 0, we replaced the expansion medium into cardiomyocytes differentiation medium containing the GSK3β inhibitor. On days 1-2, we observed that 30%~40% of the cells in the medium shown in medium and 50~60% of the cells in the medium were died and detached from the surface. However, the center of the colony of living cells were getting thicker and became compact. These cells were differentiated into cardiomyocytes on days 5-6. On day 8-10, we successively observed the contracting colonies on each biomaterial surface.

CONCLUSIONS: We successfully screened the optimal elasticity of bio-materials, preferable nanosegments immobilized on the biomaterials as well as the cell culture medium for the optimal differentiation of hPSCs into cardiomyocytes. This system will be used for developing for cell sorting system, which will be a great benefit to its clinical application in regenerative medicine.

$^1$Regenerative medicine & Stem cell Laboratory (RMS), Department of Biomedical Engineering, Indian Institute of Technology Hyderabad, Hyderabad, India

INTRODUCTION: 3D printing or additive manufacturing is employed to manufacture complex anatomical shapes and patient specific tissue grafts based on CT/MRI scans. Strontium promotes osteoblasts proliferation and inhibits osteoclasts. Magnesium Induces nitric oxide production in endothelial cells and promotes angiogenesis.

METHODS: Sr$^{2+}$ and Mg$^{2+}$ doped calcium deficient apatite (CDA) powders were synthesized by wet chemical precipitation method. Ceramic ink was formulated and scaffolds were 3D printed using extrusion 3D printer. The 3D printed green bodies were tested for invitro biocompatibility, osteogenic differentiation and angiogenetic potential.

RESULTS & DISCUSSION: SEM micro graphs (Fig 1A & B) of 3D printed structures show complete removal of binder used to formulate the ceramic ink and tightly packed and intact external morphology without any cracks. The hUMSCs seeded on top of the 3D printed structures show good proliferation and biocompatibility after 2 days of culture as evident from live/dead staining (Fig 1(C, D & E)). Alamar blue dye reduction assay confirm significant increase in metabolic activity after seven days of culture. ALP staining indicates increased osteo differentiation with increased Sr$^{2+}$ and Mg$^{2+}$ ions concentration. In vitro tube formation assay performed using media extracts of Sr and Mg doped CDA shows increased sprouting, tube length and diameter formed by Endothelial cells on Matrigel matrix after 6 hours when compared to CDA.

CONCLUSIONS: Co doping these two elemental ions in mechanically stable CDA show a synergistic effect on angiogenesis and osteogenesis simultaneously and can be a suitable candidate for bone tissue engineering. As the ink formulated using the prepared CDA powders is effortlessly 3D printable with complex internal architecture this material can be employed to fabricate patient-specific bone defects.

Figure 1: SEM images of Sr$^{2+}$ and Mg$^{2+}$ doped CDA linier and hexagonal infill (A, B). Live dead images of CDA (C), 0.03 M Sr$^{2+}$ and Mg$^{2+}$ doped CDA (B) and 0.06 M Sr$^{2+}$ and Mg$^{2+}$ doped CDA (C) after 72 hours.

We describe a novel patented technology developed in our laboratory based on a fibrin-alginate mesh that is pro-angiogenic and shows excellent cell attachment and infiltration properties. The first product developed using this technology is a dermal replacement scaffold called Smart Matrix®. Advantageously, this fibrin-alginate technology can be combined with synthetic polymers, either inert (i.e. silicones) or bioactive (i.e. polycaprolactone, PCL) in various shapes (sheets, 3D structures), or osteogenic components for repair and regeneration of various tissues. Extensive in vitro and in vivo analysis has shown that Smart Matrix® allows a rapid initial infiltration of cells and blood vessels [1]. The product has gone through detailed structural characterization using techniques like SEM, histological analysis, laser scanning confocal microscopy and AFM. The results have suggested that the material is highly porous, and the interconnected pores are gradient in nature. The cellular behavior towards the biomaterial has been confirmed through numerous cell viability assays, cytotoxicity assays and angiogenic assays including the very popular chick chorioallantoic membrane (CAM) assay. To further expand the applications of the technology, a novel two-component dermal scaffold for the treatment of pressure sores was designed using a polydimethylsiloxane (Sil) backing membrane to make the dermal scaffold more robust [2]. Moreover, the fibrin-alginate mesh was combined with PCL structures for the treatment of non-union fractures: the pro-angiogenic properties of the PCL/fibrin-alginate composite scaffold were increased compared to PCL alone as shown by the CAM assay. PCL/fibrin-alginate scaffolds are currently being tested in a rat model. Moreover, the fibrin-alginate mesh has been modified by introducing an osteogenic element into the mesh to be used as a bone void filler. We present here a pro-angiogenic fibrin-alginate technology for repair and regeneration of soft and hard tissues. The first product of this technology is currently undergoing clinical trials. Future development will see its combination with 3D printing for development of custom-made implants.

Role of dexamethasone and (+)-ZK 216348 during chondrogenic fate in bone marrow stem cells
V. Basoli 1, E. Della Bella 1, M. Alini 1, M.J. Stoddart 1
1Musculoskeletal Regeneration, AO Research Institute Davos, Davos Platz, Switzerland

INTRODUCTION: The chondrogenic commitment in vitro requires the use of glucocorticoids (GCs)[1]; however, the exact role of them in this process is still not clear. Here, we investigate how glucocorticoids play a role during chondrogenesis in the presence or absence of dexamethasone (DEX) or (+)-ZK 216348[2], a novel synthetic glucocorticoid agonist that modulates NF-kB pathway.

METHODS: We induced chondrogenesis in hBMSCs (n= 6, obtained with full ethic consent) using 10 ng of TGFβ for the 2 hours in the presence or absence of DEX (100nM) and (+)-ZK 216348, then for 7, 14 and 21 day respectively. The gene expression analysis by RT² array was performed after 2h and respective days for the interesting genes. GAG and Histology using Safranin-O and IHF for Col 2 were analyzed after 21 Days.

RESULTS & DISCUSSION: GC treatment by (+)-ZK 216348 downregulated gene expression of cartilage matrix components Collagen Type 2, aggrecan, and collagen type X and decreased cartilage matrix-sulfated proteoglycans and GAG production. Interestingly, chondrogenic commitment in the absence of conventional DEX used at 100 nM showed an increase of SOX9 expression in the early moment of differentiation compared to hBMSC pellets in the presence of DEX.

CONCLUSIONS: The use of GC treatment during chondrogenic commitment strongly influences stem cell fate. The use of (+)-ZK 216348 counteracts differentiation, potentially by controlling NF-kB translocation and interfering with gene expression activation of genes involved in chondrogenesis. Our results suggest that the transactivation pathway plays a role in chondrogenic differentiation. This provides new insights for understanding the molecular mechanisms behind MSC fate in vitro.

INTRODUCTION: 3D live bioimaging of in-vitro cell culture requires invasive staining which often affects the physiology of the investigated process and may result toxic in the long run. To avoid these effects, we used label-free multimodal microscopy, to observe mesenchymal stem cells (MSC) cultured inside a biomimetic 3D microscaffold called Nichoid, capable of maintaining cells stemness through architectural cues.

METHODS: Nichoid scaffolds were fabricated by multi-foci direct laser writing. Parallelization was achieved by adding a spatial light modulator to the laser fabrication setup. MSC at a density of 20,000 cells/cm² were seeded on the scaffolds and cultured for 3 weeks with adipogenic induction medium. Cells were observed directly in the scaffolds with coherent Raman microscopy and TPEF microscopy combined in the same setup, at different time points during culture. Images were elaborated with Matlab and Fiji-ImageJ.

RESULTS & DISCUSSION: Parallelized multi-foci fabrication of Nichoids allowed to greatly reduce the fabrication time of these micro structured substrates, overcoming the main limitation of this fabrication technique by increasing the number of samples available for cell culture in a short time. MSCs expansion and differentiation in the 3D environment showed lipid vesicle formation and their distribution through Nichoid pores. Coherent Raman microscopy allowed to clearly reconstruct fat droplets inside the microstructure in their whole volume, excluding any other signal. This technique allowed to filter out the autofluorescent signal of the Nichoid scaffold, that can be acquired by two-photon acquisition.

CONCLUSIONS: Our experiments suggest that multimodal label-free microscopy is a promising tool for observation of the evolution of cell culture in-vitro in a 3D environment.

Tendon biomimetic scaffolds influence amniotic epithelial stem cells genotype and phenotype towards the tenogenic lineage

V. Russo¹, M. El Khatib¹, A. Mauro¹, P. Berardinelli¹, M.R. Citeroni¹, O. Di Giacinto¹, M. Turriani¹, M. Ancora², M. Schnabelrauch³, R. Wyrwa³, J. Weisser³, B. Barboni¹

INTRODUCTION: Tendon injuries have prompted researchers to find alternative solutions in the field of tissue engineering. Two aspects are crucial and must be taken into consideration to accelerate tendon regeneration: the design of a tendon biomimetic scaffold and the choice of the stem cell source. In this context, amniotic epithelial stem cells (AECs) represent an attractive cell source due to their high tenogenic attitude. Since it has been already demonstrated that PLGA is biocompatible for AECs; in this study we fabricated with this biopolymer a tendon biomimetic scaffold, with highly aligned fibers, and explored its biomechanical properties and tenogenic potential on AECs.

METHODS: Highly aligned and random, used as control, PLGA electrospun scaffolds (PLGA-HA and PLGA-R, respectively) were fabricated using the electrospinning technique. Their ultrastructure (SEM) and their mechanical properties were evaluated. Moreover, ovine AECs were seeded onto each scaffold type (0.5cm×1cm), and then cultured. Subsequently, we compared their viability (Calcein AM and propidium iodide), morphology and proliferation index (48h culture), as well as gene and protein expression for epithelial mesenchymal transition (EMT) (24h, 48h, and 8 days culture). Finally, it was also investigated the effect of fetal tendon co-culture [2] on teno-differentiation of AECs seeded onto both scaffold types (14 and 28 days of culture).

RESULTS & DISCUSSION: Scaffolds’ mechanical properties showed that the alignment of fibers resulted in a higher tensile stress and strain compared to the PLGA-R scaffolds (p<0.05). AECs were viable on all type of PLGA scaffolds, whereas AECs proliferation was significantly higher on PLGA-R rather than the PLGA-HA scaffolds. Interestingly, cells on PLGA-HA, acquired an elongated morphology, spindle-like tenocyte, just after 24h culture, whereas AECs on PLGA-R retained their cobblestone typical morphology. Morphological changes were also genotypically and phenotypically confirmed by the upregulation of EMT-related genes (Vimentin and Snail mRNAs) (p<0.05), and α-SMA (mesenchymal marker) protein expression, in parallel to Cyto-8 (epithelial marker) downregulation of AECs seeded on PLGA-HA respect to PLGA-R engineered scaffolds (p<0.05). AECs cultivated on PLGA-HA expressed collagen type I (COL1), the main protein of a tendon, in their cytoplasm during the first 24h of culture. This result was also confirmed by analyzing the mature tendon specific markers COL1 and TNMD gene expressions that were significantly higher in PLGA-HA bio-hybrid scaffolds compared to those in PLGA-R (p<0.05). After 28 days’ culture, COL1 and TNMD mRNAs reached their highest values compared to PLGA-R (p<0.05), and COL1 protein became extracellular. Tenogenic AECs differentiation was even accelerated when PLGA-HA bio-hybrid scaffolds were co-cultured with fetal tendon explants. Indeed, cells were able to express COL1 and TNMD mRNAs at their highest levels and COL1 already at day 14 on PLGA-HA scaffolds.

CONCLUSIONS: PLGA-HA electrospun scaffolds bio-mimic tendon biomechanics and structure. Indeed, these features are able to induce an early EMT and promote AECs teno-differentiative potential that is even accelerated when co-cultured with fetal tendon explants. In conclusion, PLGA-HA electrospun scaffolds have great teno-inductivity and could serve as tendon construct.
SilkBridge: A novel biomimetic and biocompatible silk-based nerve conduit

INTRODUCTION: In this study, silk fibroin was used to manufacture a nerve conduit (SilkBridge) characterized by a novel 3D architecture. Results of morphological, physical, and mechanical characterization of the SilkBridge are presented. In vitro cell interaction studies were performed using glial RT4-D6P2T and neuronal NSC34 cell lines. In vivo pilot trials for the repair of rat median nerve are also reported.

METHODS: The SilkBridge was manufactured according to a patented technology (WO 2016/067189 A1) and fully characterized. In vitro cell tests were performed using RT4-D6P2T, a schwannoma cell line and Mouse Motor Neuron NSC-34 cell line. After 2, 4, and 6 days (RT4-D6P2T cells) and after 5 days (NSC-34 cells) of culture cells were analyzed to evaluate adhesion, proliferation, and differentiation. In vivo nerve regeneration assays were performed on 4 adult females Wistar rats. A 12 mm long gap in the median nerve was repaired with SilkBridge. After 2 weeks post-operative, regenerated nerves analyzed by light and confocal microscopy, Masson’s trichrome staining, immunohistochemistry, high resolution light and electron microscopy.

RESULTS & DISCUSSION: The 3 cm long SilkBridge with an inner diameter of 1.6 mm and a wall thickness 0.52 mm consists of two ES (inner and outer) and one TEX (middle) layers perfectly integrated at the structural and functional level, able to respond as a single body to mechanical stresses, without showing slipping or separation between adjacent layers, thus avoiding the emergence of biomechanical mismatch at the implantation site. The manufacturing technology conferred high compression strength (up to 190 N/m at 60% strain under submersed state at 37°C), higher than commercial collagen-based nerve conduits, thus meeting requirements for clinical application, being able to withstand reported physiological and pathological compressive stresses. In vitro direct contact assays of glial RT4-D6P2T and neuronal NSC-34 cell lines with SilkBridge revealed that the material is capable to sustain cell proliferation; glial cells increased their density and organized themselves in a glial-like morphology. Neuronal NSC-34 cell line showed a natural tendency to differentiation, with a more pronounced neuritic elongation respect to the control conditions. In vivo tests at two weeks from surgery showed that several cell types colonized the lumen of SilkBridge. Cells and vessels were also visible between the different layers of the conduit wall. Moreover, the electron microscopy analysis allowed to reveal the presence of few regenerated myelinated fibers with a thin myelin sheath at proximal level.

CONCLUSIONS: SilkBridge shows an optimized balance between biomechanical and biological properties. Both in vitro and in vivo results demonstrated that SilkBridge is a valid and biomimetic substrate for cells to grow on. In vitro, nervous cells are able to differentiate and start the fundamental cellular regenerative activities, while in vivo studies showed a perfect cellular colonization of the conduit and the progressive growth of the regenerating nerve fibers. Long-term in vivo studies are in progress.
Hyaluronic acid hydrogels with prolonged antibacterial activity

INTRODUCTION: Implantation of biomedical devices is often followed by excessive immune response to the implant, as well as by bacterial, yeast and fungal infections. Inflammation and infection may seriously affect implant functionalities and even lead to their failure. To address these issues, our group is developing antimicrobial and anti-inflammatory coatings made of polypeptides and polysaccharides [1-3]. Recently, we developed hyaluronic acid (HA) hydrogels that can be loaded with polyarginine (PAR), a homopolypeptide, and provide a long lasting antibacterial effect. Such hydrogels can be deposited onto wound dressings and mesh prosthesis to prevent infections, thus improving tissue regeneration and/or implant integration.

METHODS: To fabricate HA hydrogels, HA solution was cross-linked with BDDE (1,4-butanediol diglycidyl ether). After cross-linking, the hydrogels were cut into 4 mm diameter pieces and loaded with 0.05 to 1 mg/mL PAR. For antibacterial assays, Staphylococcus aureus suspension was added to the wells of a 24-well plate containing HA hydrogels loaded with PAR. Antibacterial effect of HA-PAR hydrogels was quantified by measuring OD 620 nm after 24h of bacterial culture. After each measurement, fresh bacterial suspension was added.

RESULTS & DISCUSSION: Loading of HA hydrogels with PAR was first characterized by confocal microscopy (data not shown). Then, antibacterial activity of HA-PAR hydrogels was studied. Hydrogels loaded with higher PAR concentrations (0.5 and 1 mg/mL) maintained their antibacterial activity for 8 days. Interestingly, the antibacterial activity depended on PAR length, PAR with 30 arginine residues (PAR30) being the most efficient.

CONCLUSIONS: These data illustrate the ability of HA-PAR hydrogels to ensure prolonged antibacterial activity.

INTRODUCTION: In order for engineered tissue grafts and eventually organs to successfully integrate in a clinical setting, a functional vascular network is imperative. Current artificial vascular networks are insufficient in scale, poorly controlled regarding their sprouting length and direction and current biofabrication methods fail so far to mimic the dynamic process which occurs in nature¹. Recently, it has been observed that embryonic tissue acts as a jammed suspension which can be locally unjammed by cellular forces. Embryonic vascularization occurs within this mechanical environment. In this work in order to mimic the embryonic environment, we created granular bioinks of different material compositions, which can be locally unjammed by HUVEC/SMC cells for the purpose of 3D printing microvascular structures.

METHODS: For the patterning phase of the granular inks we tested blended Agarose-Collagen conjugate particles with a diameter of 25μm. For the preparation the alginate granular ink, in-Air microfluidics technology were produced with the In-Air Microfluidics technology, and subsequently coated with 5% w/v collagen solution to allow DCAM cell adhesion onto the particles. 1:1 Human umbilical vascular endothelial cells (HUVEC) / Smooth Muscle Cells (SMC) Spheroids, functioning as the 3D tissues were used to dope randomly the granular ink in different ratios to find the maximum concentration of cells/ml that can be printed. SMC and HUVECs cell high concentration pellet was also mixed with the granular ink particles in order to find the maximum concentration of cells that can be loaded in the interstitial space of the granular ink. Optical and confocal microscopy was employed in order to characterize the samples.

CONCLUSIONS: The ability to 3D print and pattern microvascular constructs through granule size and composition modification and which offers an embryo-like mechanical environment, establishes that granular inks are a potent alternative to their shear thinning hydrogel counterparts.

Figure 1: 3D printed granular agarose ink(red) doped with FITC dextran labelled 75μm 0.25% alginate microparticles(green) as proof of concept of a 3D printable doped granular ink.

University Health Network, Toronto, ON M5T 2S8, Canada

INTRODUCTION: Biohydrogel design is a booming field of research. Over the last 10 years, many
new crosslinking strategies have been proposed to allow 3D cell culture, cell/drug delivery or
bioprinting, holding the promise of versatile and user-friendly platforms to come for use by biologists
and clinicians. [1-2] Yet, most of the existing systems (i) require external stimuli or
catalysts/activating agents (e.g., photochemistry), (ii) are not entirely biorthogonal or compatible with
physiological conditions (e.g., hydrazone, disulfide), or (iii) have inherent limitations such as limited
stability or slow gelation rate (e.g., Diels-Alder). Thus, a hydrogel that would be fully tunable, fast-
gelling, biocompatible and, yet, easy to synthesize and use, remains to be designed.

In this context, we hypothesized that a novel hyaluronan (HA)-based hydrogel that uses the inverse
Electron-Demand Diels-Alder (iEDDA) «click » reaction as a crosslinking mechanism, would meet
all the design criteria. As part of our strategy, we hypothesized that crosslinking two HA components
together, as opposed to using a synthetic crosslinker such as polyethylene glycol, would greatly
reduce the gelation time and offer new possibilities.

METHODS: The components of this new class of HA-based hydrogels were easily synthesized in
single-step reactions from commercially available compounds. Optimizing the HA MW, component
ratio and polymer content, we successfully designed fast-gelling hydrogels that form under
physiological conditions. Interestingly, the optimized hydrogels were non-swelling, transparent and
enzymatically biodegradable within days.

RESULTS & DISCUSSION: To demonstrate their versatility, the newly designed hydrogels were
tested as matrices for 3D cell culture and explant imaging in the context of retinal degeneration
investigation. Using two retinal cell types (αRPE-19 cells and Nrl⁻/⁻ photoreceptor cells), iEDDA
hydrogels were shown to be cytocompatible. The evaluation of 3D cell distribution confirmed the
ease of mixing, and showed that optimal encapsulation requires gelation time < 10 min. The HA-
based hydrogels were then tested for 2-photon retinal explant imaging. Compared to gold standard
agarose thermogels, our new hydrogels best preserved retinal tissues, and prolonged remarkably the
fluorescence of GFP-labeled explanted retinas, allowing 2-photon imaging over days vs hours.
Finally, subcutaneous injections of iEDDA hydrogels were performed, confirming proper gelation in
vivo and, thus, their possible use as drug/cell delivery vehicles. While we explored their potential in
the context of innovative ophthalmological investigation, iEDDA HA-based hydrogels constitute a
novel hydrogel platform for in vitro and in vivo applications.

INTRODUCTION: Liposomes are among the most used delivery vesicles. However, their adsorption on solid surfaces usually results in their spontaneous reorganization and formation of a supported lipid bilayer [1,2]. This reorganization compromises the compartmentalization and change the uptake and release of bioactive agents. We hypothesize that soft layer-by-layer (LbL) supports would minimize colloidal instability of liposomes upon adsorption and promote supported vesicular layers (SVL).

METHODS: Gold-coated quartz crystals were modified with 3 bilayers of cationic poly-L-lysine (PLL) and anionic hyaluronic acid (HA). A top layer of cationic liposomes loaded with Nile Red (d=120 nm, ζ-potential=10 mV) was added, followed by 2 HA/PLL bilayers. The assembly was monitored by quartz crystal microbalance with dissipation (QCM-D). The encapsulation efficiency (EE) and release to NaCl 0.15 M were quantified by fluorescence spectroscopy.

RESULTS & DISCUSSION: Our QCM-D data demonstrated that indeed a phospholipid bilayer is formed upon adsorption of the liposomes on bare gold crystals. When the deposition was carried out on soft LbL substrates instead, we observed adsorption of intact spherical liposomes. We determined an average EE of 5.4 ng/cm² for these constructs and 12% release after 1 h. Further coating of the constructed SVL with HA/PLL bilayers did not compromise their stability and increased the diffusion barrier: only 4% (three fold less) of Nile Red were released from the SVL coated with 2 HA/PLL bilayers. This result showcases that the release can be controlled by additional top layers but also the protective efficiency of this coating as compared to free liposomes in aqueous suspension (~29%).

CONCLUSIONS: SVLs show promise for compartmentalized 2D films where small amounts of biomolecules are encapsulated for diagnostic and therapy. Liposomes will allow expanding these systems further to bioactive hydrophilic species.

There is an uneven increasing worldwide shortage of transplantable tissues (in the US, approximately 100,000 individuals are waiting for a kidney transplant) (1) for the treatment of cancer and chronic disease conditions. And this trend is strengthened by the population aging, worldwide. The use of cellular or tissue engineering products is one solution to cover these unmet medical needs. They started to be developed since the late 70’s, but still marginally used in the clinics, essentially due to high selling prices and the lack of reimbursement in most cases. Cellular or tissue engineering therapies are designated as ATMPs (Advanced Therapy Medicinal Products) in Europe or Biologic/RMATs (Regenerative Medicine Advanced Therapies) in the USA. They can be divided into two main groups according to the cell origin: (autologous) or (allogeneic). These two groups are differentiated by their mechanism of action, manufacturing processes and, business models. Autologous cell-based therapies are usually produced at small-scale (scale-down), in dedicated suites, with centralized or localized manufacturing facilities at point-of-care. Allogeneic therapies have the potential to be produced at large scale (scale-up) in large facilities where they can be stored and shipped to the users at the time of clinical needs for patients. While allogeneic manufacturing allows cost reduction due to large volume, both groups require numerous human resources which represent the most part of the cost of goods (COGs) for manufacturing. This prevents widespread clinical adoption of these therapies. The development of automatization is then seen as a relevant option for both reducing COGs and improving the quality of cells with higher batch to batch reproducibility. Automation should deliver three major outcomes: 1- Improving safety by using disposable closed system with fewer or no manual operations, 2- Improving cell culture efficiency by reducing manufacturing time while optimizing the quality of amplified cells, 3- Lowering cost by reducing culture time and human resources. Automation should play a key role in the development of cellular and tissue therapies by creating standardized processes that can be replicated everywhere, without neglecting the quality of the product and aligning with regulatory guidelines of ATMPs and, RMATs. And it is even seen as a cornerstone to guarantee the economic viability of tissue engineered and cell therapies to be delivered in a more cost-effective way. This is mandatory for reimbursement which should lead to larger market adoption.

INTRODUCTION: There is a great interest in the development of in vitro alternatives to animal testing by using tissue-on-chip technologies [1]. Here, we developed an Intestine-on-a-chip (In-OC) platform used to increase the epithelial differentiation on a cell-instructive stromal equivalent fabricated by using a bottom-up approach technique [2, 3].

METHODS: Porous gelatin microscaffolds were used to culture human intestinal subepithelial myofibroblasts to make intestine-microtissues that were further used as building-blocks to construct a 3D stromal intestine equivalent (3D-ISE) [2]. To obtain the complete model, human colon-carcinoma cells (Caco-2) were layered and induced to differentiate on 3D-ISE into a properly designed chip. In-OCs were obtained by using replica molding of PDMS; a polycarbonate membrane (0.4µm pore) separated the lower layer consisting in a single chamber from the upper chamber on which is placed the 3D-ISE. Immuno-histotypical, ultra-structural analyses and Trans-epithelial electrical resistance (TEER) measurements were performed to assess the differentiation markers expression and to evaluate the epithelial barrier integrity. The auto-produced collagen signal was also examined by using multiphoton microscopy combined with second harmonic generation imaging.

RESULTS & DISCUSSION: The H/E staining of 3D-human intestine-equivalent showed that the villous-like thickness increased in In-OC samples respect to the static culture. The epithelial differentiation markers were analyzed by confocal (villin) and ultrastructural (SEM) analyses. TEER induction revealed the enhancement of the barrier properties during the dynamic culture confirmed by ZO-1 intensity enhancement. SHG signal indicated an increase in collagen remodeling in In-OC respect to the static conditions.

CONCLUSIONS: Taken together these data indicated that In-OC allows to obtain a better full thickness equivalent human tissues in a shorter time, that can be employed in the future as an effective alternative to animal model for drug testing.

INTRODUCTION: Drug development is a high-costly process and may last 7-10 years with no guarantees for the final drug approval and efficacy particularly for cancer treatment. There is an urgent need to develop the new tools to be able to copycat the tumor microenvironment and more realistic drug-screening platform to predict the drug efficacy and toxicity. Biomaterials support the growth of cancer cells together with the other cellular and acellular players, which offer different options to recapitulate the tumor micro-environment [1, 2]. In this work, we develop a 3D in vitro cancer model based on naturally-derived silk protein fibroin biomaterial. Fibroin shows good biocompatibility, suitable mechanical properties, and tunable biodegradability. Silk fibroin-derived freeze-dried scaffolds are produced in order to recapitulate faithfully the tumor microenvironment.

METHODS: 2 % silk fibroin solution is used to fabricate the scaffolds. The breast cancer cells (MCF-7) and normal mammary fibroblast are seeded or embedded on the scaffolds. The cell proliferation is monitored by means of Alamar blue assay at different time points for 14 days. 3D breast cancer model morphology is observed by confocal microscopy. The gene expression modulation concerning the extracellular matrix markers is evaluated by means of qRT-PCR. Further, 3D bioengineered breast cancer models are treated with doxorubicin. The cell growth inhibition is assessed at 24, 48 and 72h post-treatments.

RESULTS & DISCUSSION: Silk fibroin scaffolds support the proliferation of the cancer cells and fibroblasts. The growth of cells is enhanced when cancer cells and fibroblasts are seeded together (p<0.001). Histological staining shows 3D cell organization. MMP-1, MMP-2, MMP-3, Col-1 and fibronectin expressions are upregulated in co-culture (p<0.001). Doxorubicin treatment reduces the proliferation of cells proliferation. However, higher doxorubicin concentration is needed to kill the cancer cells when they are in co-culture with fibroblasts.

CONCLUSIONS: The platforms designed may represent promising model for understanding the crosstalk between cancer cells, fibroblasts and extracellular matrix. The developed 3D in vitro tumor tissue model is expected to be an appropriate platform for drug-screening.

INTRODUCTION: Chondrogenically primed Mesenchymal Stem Cells (MSCs) have been shown to form bone in vivo via the endochondral ossification pathway [1]. Nevertheless, the outcome is highly influenced by donors’ age and consequently MSC differentiation capacities. Here, we study the potential of chondrogenically primed paediatric MSCs (pMSCs) for bone formation in an immune allogeneic setting within a humanised mouse model.

METHODS: 21 day chondrogenically primed pMSCs were subcutaneously implanted in IL2Rγ-/- RAG2-/- immunodeficient mice for 8 weeks. After that time, 5x10⁶ allogeneic human peripheral blood mononuclear cells (PBMCs) were intraperitoneally injected for 4 weeks. Bone formation was quantified by uCT imaging for up to 12 weeks. Upon retrieval, bone structure was assessed in the constructs by immunohistochemistry (IHC). Human engraftment was determined in blood and spleen by FACS. Human immune cell infiltration in the constructs was analysed by IHC and PCR.

RESULTS & DISCUSSION: uCT scans showed bone formation at 8 weeks upon implantation until the endpoint of the experiment (12 weeks). FACS results revealed successful human PBMC engraftment in the humanised animals. CD45⁺ human cells were detectable 4 weeks after humanisation in blood and spleens, and no significant differences were observed in the CD45⁺ percentages between the humanised animals regardless of the presence of the bone constructs (2.6±0.7 versus 4.4±1.4 in blood, and 31.7±4.9 vs 36.9±3.9 in spleens). Upon retrieval of the constructs, H & E staining revealed a bone like structure. Human immune T cell infiltration in the humanised mice was identified by CD3 human IHC. In these animals, expression of CD4 and CD8 T cells was detected by PCR in the constructs, as well as CD8 cytotoxicity associated markers PRF-1 and GZMB.

CONCLUSIONS: Here, we show that chondrogenically primed pMSCs are able to form bone in vivo that is maintained in a successfully engrafted allogeneic humanised animal model. No evidence of a destructive immune response was detected in blood nor spleens. Nevertheless, human allogeneic T cells infiltrated in the bone structure of the allografts upon 4 weeks of humanisation. All together, these results illustrate the potential of pMSCs for bone formation via the endochondral ossification process in the presence of a donor mismatched immune system. However, further investigation into possible cytotoxic T cell local responses towards the allografts is required.

INTRODUCTION: The development of 3D in vitro cancer models that mimic the microenvironment of human tumors is a promising approach to accelerate the discovery of novel anti-tumor therapies [1,2]. Herein, we engineered 3D scaffold-based in vitro osteosarcoma cancer models by using GelMA and Matrigel™ ECM-mimicking hydrogel microenvironments and compared the physio-pathological features of cell-laden hydrogels (Pseudo-3D culture) with those of 3D spheroid-laden scaffolds in order to evaluate which platform could better mimic solid tumors and the biological cues of the in vivo tumor microenvironment.

METHODS: Osteosarcoma 3D cancer models were established by using the MG-63 (ATCC® CRL-1427™) cell line. Cancer cells were seeded within GelMA 10 % (w/v) and Matrigel™ hydrogels. At the same time, MG-63 3D spheroids were formed by the force-floating technique in ultra-low adhesion 96-well plates for 7 days and were then encapsulated in GelMA or Matrigel™ hydrogels. Cells and spheroids morphology, as well as necrotic core formation were evaluated in both in vitro models at 7, 14 and 21 days.

RESULTS & DISCUSSION: 3D tumor spheroids cultured in ECM-mimicking hydrogels maintained their spherical spheroidal morphology acquired during force-floating aggregation and exhibited necrotic core formation. On the other hand, the pseudo-3D culture did not exhibit the typically necrotic core and the single macrostructure of a solid tumor mass.

CONCLUSIONS: Overall, the pre-formed 3D spheroids laden in ECM-mimetic hydrogels recapitulate better solid tumor hallmarks and represent a more promising model for drug screening at later disease stages.

ACKNOWLEDGEMENTS: Financial support was received from ERC for project ATLAS (ERC-2014-ADG669858), for project Microbone (PoC-2017-7897602017), and from FCT as a Post-Doc grant (SFRH/BPD/119983/2016, Vitor Gaspar).

INTRODUCTION: The progress of active methodology to heal a large-scale muscular defect is still a topic of noteworthy concern, and a possible alternative consists of an injectable dosage form to be directly inserted into muscle. Gellan Gum (GG) is commonly used hydrogel owing to its appropriate jellifying temperature (37ºC) [1]. However, its cell adhesive properties can be enhanced by adding sulfonyle functional group which in turn allow the binding of a desired cell adhesive peptide important for cell encapsulation traits. Herein, we propose GG-based hydrogels with tailorable physical-chemical and mechanical features, biofunctionalized with muscle-derived laminin peptide sequences specifically selected to mimic the muscle extracellular matrix and promote skeletal muscle cell binding.

METHODS: GG polymer was chemically functionalized with divinyl sulfone (DVS) groups then reacted with three specific peptides (CIKVAVS (V), KNRLTIELEVRTC (T), RKRLQVQLSIRTC (Q)) by a one-step reaction. The efficiency of the reaction was determined by 1H NMR and µ-BCA assay. Different hydrogel formulations were prepared by mixing GG-DVS-Peptide and GG at different amounts and characterized in terms of injectability, mechanical properties, swelling and molecules diffusion. Murine skeletal muscle cells (c2c12) were encapsulated within hydrogels, and cell viability, adhesion, spreading and differentiation was evaluated after 1, 7, 14 and 21 days, by phalloidin, calcein/PI staining and immunocytochemistry for Myosin Heavy Chain (MYH).

RESULTS & DISCUSSION: Biofunctionalization of GGDVS with X, Y and Z peptides was confirmed by 1H NMR and µBCA yielding a conjugation efficiency of V=47.34%, T=31.57% and Q=92.65%, respectively. Hydrogel’s properties varied with the formulation; all hydrogel formulations were injectable, allowed the diffusion of molecules up to 250 kDa, presented a deswelling ratio up to 15% and an elastic modulus ranging from 10 to 100 kPa. Cell death (<50%) was detected after 1 day of encapsulation but the majority of the cells were alive after 7 days. Since day 1, cells started spreading most remarkably in hydrogels with higher polymer amount and depicting higher mechanical properties. In these hydrogel formulations, cells proliferated and elongated showing MHC expression at day 14.

CONCLUSIONS: GG-based hydrogels showed tailorable physical-chemical and mechanical properties, as well as cell-binding properties that improved skeletal muscle cell performance.

INTRODUCTION: Hypertrophic chondrocytes mediate the enduring pathway for endochondral bone formation. However, challenges in tissue-engineered bone constructs include functionality under the mechanical environment inside in vivo conditions. We aim to fabricate a mechanically stable Silk fibroin (SF) carrier incorporating decellularized cartilage derived extracellular matrix (CD-ECM) and hypertrophic chondrocytes as a model of endochondral ossification and characterize superior bone-like tissue formation non-destructively in the case of in vitro studies to find the optimal time point when the constructs should be implanted.

METHODS: Human bone marrow stem cells (hBMSC’s) were seeded onto CD-ECM/SF or SF constructs and primed for 2-week chondrogenesis following a further 8-week hypertrophy or 4-week hypertrophy + 2-week osteogenesis in differentiation medium. Biochemical assays, SEM/EDX, RT-qPCR, Biomechanical tests followed by non-destructive μCT scanning were used as methods at 4 and 8 weeks to determine hypertrophy mediated ossification.

RESULTS & DISCUSSION: Calcium deposition biochemically determined increased significantly from 4-8 weeks in both SF and CD-ECM/SF constructs (p < 0.05) and retention of sGAG’s were observed in CD-ECM/SF constructs. SEM/EDX revealed calcium and phosphate crystal localization by hBMSC’s under all conditions. Compressive modulus reached a maximum of 70 KPa in 8-week hypertrophic induction group than 4-week hypertrophy+2-week osteogenesis group (p<0.05). μCT scanning at 8 weeks indicated a cloud of denser minerals in groups only induced for 8-week hypertrophic induction. Gene expression by RT-qPCR revealed that hBMSC’s expressed hypertrophic markers VEGF, COL10, RUNX2 but absence of early hypertrophic marker ChM1 and presence of later hypertrophic marker TSBS1. Further induction of osteogenesis indicated presence of osteogenic markers ALPL, IBSP, OSX under all conditions.

CONCLUSIONS: Our data indicates a new method to prime hBMSC’S into late hypertrophic stage in vitro in mechanically stable constructs for endochondral ossification mediated bone regeneration.

INTRODUCTION: Tendons require mechanical loading to maintain the homeostasis and function [1]. This study aimed to investigate if mechanical stimulation of tenocytes in 2-dimensional (2D) monoculture is able to mimic loading of the Achilles tendon in an in vivo mouse model.

METHODS: The left tibiae of female BALB/c mice (10 weeks) (n=14) were subjected to axial compression (10N, 216 cycles/day at 4 Hz) for 3 weeks. Right tibiae served as non-loaded control.

Tenocytes were isolated from Achilles tendons of female BL6J mice (26 weeks) and mechanically loaded (216 cycles, 4% stretch and 4 Hz) for various periods. Histology (n=8) was performed for in vivo loaded tendons. Gene expression was analyzed with qPCR (in vivo and in vitro) (n=6).

RESULTS & DISCUSSION: Histology: no differences in cell morphology or collagen fiber network in the in vivo loaded tendons. The expression of Scleraxis (Scx) and Tenomodulin (Tnmd) showed no significant changes between in vivo and in vitro stimulation (Fig. 1B). Significant changes in expression were found for Collagen type I (Col1), Col3 and Metalloproteinase 2 (MMP2) (Fig. 1C).

CONCLUSIONS: This study showed that gene expression of tendon markers was similar, whereas significant changes in the extracellular matrix compartment were detected between in vivo and in vitro loading. The differences might be explained by the 2D in vitro set-up [2]. In this study young and adult mice of different genetic strains were compared. It is known that age can affect gene expression in bone cells in response to mechanical loading [3], which cannot be excluded for tendon. Moreover, the loading regimes differ in duration of loading, which might also influenced the outcomes. However, this first pilot study is important for the development of an in vitro stimulation set-up of tenocytes that mimic in vivo characteristics.

ACKNOWLEDGEMENTS: The project was funded by the Berlin-Brandenburg Center for Regenerative Therapies (BCRT; Bundesministerium für Bildung und Forschung (BMBF) grant 1315848A).

INTRODUCTION: One of the most promising experimental approaches for spinal cord regeneration is transplantation of neural stem cells-containing biomimetic hydrogel with the ability to adjust the axon’s directionality.

METHODS: In vitro study was conducted using directly reprogrammed neural precursor cells (drNPCs) obtained as described earlier (J.-E. Ahlfors et al., 2012, 2018), that were cultured in PRP-based hydrogel. Anisotropically structured complex scaffold has been prepared by electospinning using mixture of recombinant rS1/9 spidroin and PCL. The in vivo experiments was conducted on 12 male rhesus macaques (2 healthy and 10 with control complete spinal cord modeled as described earlier (VP Baklaushev et. al, 2018).

RESULTS & DISCUSSION: We have designed a novel two-component matrix (SPRPix) for the encapsulation of drNPCs. The combination of PRP and spidroin promoted drNPC proliferation with the formation of neural tissue organoids and dramatically activated neurogenesis. Differentiation of drNPCs generated large numbers of βIII-tubulin and MAP2 positive neurons as well as some GFAP-positive astrocytes, which likely had a neuronal supporting function. Interestingly the SPRPix microfibrils appeared to provide strong guidance cues as the differentiating neurons oriented their processes parallel to them. Implantation of the SPRPix matrix containing human drNPCs into the brain and spinal cord of healthy Rhesus macaque monkeys showed good biocompatibility: no astroglial and microglial reaction was present around the implanted construct. Importantly, the human drNPCs survived for the 3 month study period and differentiated into MAP2 positive neurons. Monkeys with SCI after implantation of drNPCs demonstrated the recovery of paralyzed hindlimb as well as recovery of SSEP and MEP of injured pathways.

CONCLUSIONS: Tissue engineered constructs based on SPRPix exhibits important attributes that warrant further examination in spinal cord injury treatment.

INTRODUCTION: Tissue engineering promises to solve acute clinical problem – a shortage of human tissues and organs for transplantation. Traditional tissue engineering is based on using synthetic or natural scaffolds as temporal and removable supports or templetes [1]. Magnetic levitational bioassembly of 3D tissue constructs represents a novel rapidly emerging scaffold-free and label-free approach and alternative conceptual advance in tissue engineering [2,3].

METHODS: The magnetic levitational bioassembly of 3D tissue construct from tissue spheroid consists of a directional levitational assembly under the action of magnetic forces of the construct from tissue spheroids, followed by fusion of tissue spheroids collected at a specific location.

RESULTS & DISCUSSION: New magnetic bioassembler have been designed, developed and certified for life space research. Tissue spheroids (thyrospheres and chondrospheres) and magnetic bioprinter were delivered on the «Soyuz MS-11» ship to the Russian segment of the international space station in a temperature-sensitive non-adhesive hydrogel. From tissue spheroids were fabricated in a magnetic printer by 6 constructs from thyrospheres and chondrospheres. The constructs fused within 24 hours for the thyrospheres and 48 hours for the chondrospheres in a magnet field at of 37°C. Then, the fused constructs were removed from the magnetic printer and fixed with formalin. Finally, the cuvettes with the constructs were sent to Earth where histology and histochemistry of the constructs were performed.

CONCLUSIONS: Scaffold-free and label-free magnetic levitational bioassembly of 3D tissue constructs from tissue spheroids (chondrospheres) have been performed first time at the condition of microgravity.

ACKNOWLEDGEMENTS: The project was implemented with the assistance of the «Roscosmos» State Corporation, Russia.

INTRODUCTION: Cancer stem cells (CSCs) typically comprise 1%–5% of the total tumor cell population. This cell population is considered to be primarily responsible for tumor initiation, growth, and metastasis. Therefore, we develop membrane filtration and migration method to target and purify rare primary CSCs based on their high migration mobility characteristics compared with other tissue cells. Further, establish the primary colon cancer cell line

METHODS: Nylon mesh filter with pore size of 11 μm and 20 μm and PLGA-silk screen membrane with different PLGA (Sigma-Aldrich) concentration 3%, 5%, and 10% are the membrane we used in the experiment. Subsequently, primary human colon cancer cells and colon cancer cell line will pass through the membrane and then be divided into three fractions. Cells without any treatment were used as control in this experiment. Cancer stem cells marker, CD44 and CD133 will be analyzed by flow cytometry. And the malignancy index will evaluate by soft agarose colony forming assay.

RESULTS & DISCUSSION: Flow cytometry analysis illustrated that colon cancer stem cell surface markers CD44 and CD133 expression in the cells from migration method were higher than the cells from permeation and recovery solutions (Fig. 1). Soft agarose colony forming assay revealed the cells from migration method were able to form bigger size of the colonies compared to the cells from permeation and recovery parts (Fig. 2).

CONCLUSIONS: The data showed that the membrane filtration method can be used to target and purify cancer stem cells. It would be a great benefit for establishing patient-specific cancer cell line.

Figure 1: (left) Flow cytometry analysis. The cells from three fraction and non-treated cells were evaluated by colon cancer stem cell surface marker (a) CD44 and (b) CD133 expression. Figure 2: (right) Soft agarose colony forming assay. The cells were seeded on soft agarose coating dishes. After 2-4 weeks, colony formation was counted for data analysis: (a) cells in permeation part, (b) cells in recovery part, (c) cells in migration part used Nylon 11μm membranes and (d) non-treated cells.

INTRODUCTION: Tissue-engineered tumor models can better mimic in vivo tumor microenvironment and provide a more representative platform for in vitro studies and drug discovery [1]. Herein, we developed tissue-engineered breast cancer models based on three different types of materials, and further evaluated cell viability and the responsiveness to chemotherapeutic agent.

METHODS: Three derived scaffolds (decellularized lung scaffold, chitosan/gelatin scaffold, and poly-L-lactic acid scaffold) were prepared. A total of 10⁵ cells were seeded on both sides of each scaffold in 24-well plates. Dead/Live staining was conducted to assess cell viability in three scaffolds. SEM and H&E were conducted to evaluate cell growth and distribution. Ki67 immunofluorescence (IF) was determined to evaluate cell proliferation. The cell response to anti-cancer drug 5-fluorouridine (5-FU) was examined in 2D and 3D culture using Dead/Live staining and CCK-8 assay.

RESULTS & DISCUSSION: Dead/Live staining indicated good biocompatibility of the three scaffolds. SEM showed cells formed contracted tumor spheroids in three scaffolds which is significant difference compared to 2D culture. H&E assay showed cell well distributed in the skeleton and aperture of three scaffolds. IF staining showed a high expression of Ki67 in MCF-7 cells, suggesting favorable proliferative activity of cells in scaffolds. The 3D structure of tumor model was visualized by the positive Ki67, F-actin, and DAPI staining, which well depicted protein expression and cell distribution with clear architecture of three scaffolds. Cells grown in 3D exhibit stronger drug resistance compared to their 2D counterparts, no significant difference was identified in three scaffolds.

CONCLUSIONS: Overall, these 3D culture systems provide a reliable and cost-effective platform to study tumor biology and drug discovery.

ACKNOWLEDGEMENTS: Financial support was received from the National Natural Science Foundation of China (31670978/21676041), and the Natural Science Foundation of Liaoning (20180510028).

INTRODUCTION: Despite the intrinsic healing capacity of bone and modern orthopedic fixation technologies, large defects do not always heal successfully resulting in fracture non-union. Modulating the immune response to fractures might enable innovative solutions to enhance the repair of large bone defects. Administration of interleukin-1 receptor antagonist (IL-1Ra) can enhance bone healing in mouse calvarium [1]; however, its therapeutic efficacy in long bone defects, which heal by endochondral ossification, and its optimal course of administration have yet to be identified. Thus, the overall objective of this study is to investigate the efficacy of IL-1Ra to enhance long bone healing.

METHODS: To determine the optimal mechanical fixation to promote endochondral ossification in an osteotomy model, 2 mm femoral osteotomies were carried out in Fischer 344 rats and fixed with either a thin 1.25 mm PEEK plate, a thicker 2.00 mm PEEK plate, or an external fixator, while histology was carried out on samples collected from animals euthanized 10 days post-surgery to check for callus formation. 4-point bending and torsional tests were also carried out on the individual fixators to determine their relative stiffness. To assess endogenous IL-1β and IL-1Ra levels up to 14 days post-osteotomy, a second round of osteotomies was carried out using the optimal plate and cytokine levels were assessed 3, 7, and 14-days post-surgery using ELISA. To assess the healing capacity of IL-1Ra, a thermo-responsive hyaluronic acid-based scaffold (T-HyA) is currently under development for the controlled delivery IL-1Ra.

RESULTS & DISCUSSION: Fixation of a 2 mm femoral osteotomy using a 1.25 mm PEEK plate led to significantly higher levels of systemic IL-1β and greater callus formation observed 10 days post-surgery compared to when fixed using a 2.00 mm PEEK plate, or an external fixator. Bending and torsional testing of the individual plates shows that the 1.25 mm plate is less stiff compared to the thicker 2.00 mm plate and the external fixator. Local IL-1β concentration was seen to decrease 7 days post-surgery, while local IL-1Ra concentration drastically increases afterwards. Release kinetics of IL-1Ra from T-HyA show that after a small burst release, >80% of the loaded protein is retained and released only after enzymatic digestion of T-HyA, while the bioactivity of the retained IL-1Ra was confirmed using HEK-Blue-IL-1β cells.

CONCLUSIONS: A long bone defect model has been optimized to mechanically induce healing via endochondral ossification while a thermo-responsive natural polymer-based scaffold has been developed for the controlled delivery of IL-1Ra. Future work will assess its efficacy to enhance healing.

INTRODUCTION: Adult articular cartilage mechanical functionality is dependent on the unique zonal organization of its tissue. The phenotype of cartilage derived from MSCs has been reported to be influenced by the microenvironmental biophysical cues, such as the surface topography and substrate stiffness [1]. In this study, the application of these pre-differentiated cells for cartilage repair was explored with the in vitro optimization

METHODS: Specific nano-topographic patterns on polymeric substrate were generated by nano-thermal imprinting on the PCL surface. Human bone marrow MSCs seeded on these surfaces were subjected to chondrogenic differentiation and the phenotypic outcome of the differentiated cells was analysis. The ability of these pre-differentiated MSCs on different nano-topographic surfaces to form zonal cartilage was verified in in vitro 3D hydrogel culture and applied in rabbit osteochondro defect model.

RESULTS & DISCUSSION: Nano-topographical patterns triggered MSC morphology and cytoskeletal structure changes, and cellular aggregation resulting in specific chondrogenic differentiation outcomes. MSC chondrogenesis on nano-pillar topography facilitated robust hyaline-like cartilage formation, while MSCs on nano-grill topography were induced to form fibro/superficial zone cartilage-like tissue. the nano-topography pre-differentiated cells possessed phenotypic memory, forming phenotypically distinct cartilage in subsequent 3D hydrogel culture. Lastly, implantation of the bilayered hydrogel construct of superficial zone-like chondro-progenitors and middle/deep zone-like chondro-progenitors resulted in regeneration of phenotypically better cartilage tissue with higher mechanical function.

CONCLUSIONS: Our results demonstrate the potential of nano-topographic cues in guiding the differentiation of MSCs to chondrocytes of a specific phenotype. Implantation of these chondrocytes in a bilayered hydrogel construct yielded cartilage with more normal architecture and mechanical function. Our approach provides a potential translatable strategy for improved articular cartilage regeneration using MSCs.

INTRODUCTION: The dismal success rate of preclinical drug candidates [1] and even surprisingly lower preclinical 5% success rate of cancer drug candidates compounds reaching the clinic [2] is at least in part due to the very complex nature of cancer pathophysiology where a complex mix of factors can lead to resistance to small molecule drugs in human patients. These can include extracellular matrix and other supporting cells such as endothelial cells and immune cells, which affect cell polarity, growth characteristics, and gene expression [3]. The two-dimensional (2D) reductionist approach where cells are incubated in a mono-layer on hard plastic microtiter plates is not physiologically relevant, then must in vivo rodent models be employed to validate the potentially positive hits emerging from a large primary screening campaign. Well developed and applied Three Dimensional (3D) in vitro models could be employed to bridge the gap between 2D in vitro primary screening and in vivo rodent models, by incorporating key features of in vivo tumour environment, such as extracellular matrix, co-culture, tension and perfusion, to replace several hundred rodents in the validation cascade.

METHODS: Human neural progenitor cells from middle brain (ReN VM, Merck Millipore, UK) were expanded as instructed by the supplier (Merck Millipore), and then seeded at 3000, 2000, 1000, 500 and 250 cells/well in 96-well plates. ReN VM were differentiated via growth factor deprivation and were imaged for a desired period. Radiotherapy was mimicked via gamma-radiation at 2Gy.

RESULTS & DISCUSSION: As shown in Figure 1, after 14 days of differentiation, neuron early differentiation marker (Tuj1, red) started to be expressed among the cells expressing neural stem cell marker SOX2 (green). Post-radiation effects include impaired tissue growth, and lower pluripotency and neuron differentiation marker expression were detected by immunofluorescence staining.

CONCLUSIONS: Combined with the benefit of greatly reducing the issues associated with in vivo rodent models, including overall numbers of animals, cost, ethics, and potential animal welfare burden, we fell that well developed and applied Three Dimensional (3D) in vitro models will be very compelling to provide a crucial tool to evaluate combinatorial therapies, optimal drug concentrations and treatment dosages.

Figure 1: Neural progenitor cell-originated 3D spheroids. After 14 days of differentiation, neuron early differentiation marker (Tuj1, red) started to be expressed among the cells expressing neural stem cell marker SOX2 (green).

In situ photopatterning of 3D osteocyte microenvironments
X.H. Qin¹, R. Müller¹
Presenting Author: Xiao-Hua Qin, E-mail: qinx@ethz.ch
¹Institute for Biomechanics, ETH Zurich, Zurich, Switzerland

INTRODUCTION: Osteocytes are mechanosensory cells in the bone matrix with long dendritic processes within the lacuno-canalicular network (LCN). So far, it remains challenging to construct a functional 3D osteocyte network in vitro that resemble the features of a LCN system. This limitation hampers a deeper understanding of bone biology and the development of functional bone in vitro models for regenerative medicine. Here we build microengineered bone models by interfacing high-resolution photopatterning with 3D cell culture technology. By scanning a laser beam through a 3D cell-laden matrix, canaliculi-like microchannels can be generated as physical cues to guide dendrite formation through two-photon-induced photoablation (2PiP).

METHODS: A series of protein gels with different stiffness (ca. 0.5-10 kPa) were prepared by UV-curing of gelatin methacyryloyl (GelMA). Single IDG-SW3 mouse osteocytes were photoencapsulated in GelMA gels (soft-5%, middle-7.5%, stiff-10%) at a final concentration of 1 M/mL and then cultured in differentiating media. Cell viability and morphology were assessed via live-dead and phalloidin-DAPI staining at day 1, 7 and 14. GM6001 was added as a broad-spectrum matrix metalloproteinase inhibitor to assess the effect of proteolysis on dendrite formation. Arbitrary micrometer-scale guidance channels were created inside 3D cell-laden hydrogels via 2PiP on a Nanoscribe GT 3D microprinter.

RESULTS & DISCUSSION: When embedded in 3D, osteocytes remained highly viable (>90%), demonstrating cell-compatibility of the photo-encapsulation process. Confocal live-cell tracking showed that the early formation of dendrites during 3D culture was strongly influenced by matrix stiffness: after 12h cells were able to form up to ca. 50-100 µm long processes in a soft matrix whereas cells remained round in a stiff matrix. Addition of GM6001 (10 µM) fully blocked dendrite formation, demonstrating the importance of proteolysis and matrix degradation in dendrite formation. Biomimetic microchannels were engineered inside a 3D matrix through 2PiP to foster dendrite formation. It was found that the threshold for 2PiP is greatly influenced by the amount of residual photoinitiator and processing parameters such as laser power and scanning speed. By positioning the focal spot in close proximity to live cells, user-dictated microchannels were generated at high spatial resolution. After 12h, guided formation of dendrites was observed.

CONCLUSIONS: In summary, we have developed a new method to create microengineered bone systems by using the 2PiP technique. This approach holds the potential to enable user-defined construction of 3D osteocyte networks as functional in vitro models for tissue engineering, disease modeling and drug screening.

INTRODUCTION: The application of stem cell-laden hydrogel systems has drawn increasing attention in cartilage repair and regeneration. However, slow fabrication, fast degradation and low stem cell retention rate have limited the clinical application of hydrogel systems. Herein, we developed an injectable hydrogel system based on functionalized chondroitin sulfate (CS), a cartilage specific extra cellular matrix (ECM) material, to generate a stem cell-laden structure for cartilage tissue regeneration.

METHODS: Functionalised CS were synthesised and crosslinked with hyperbranched poly(ethylene glycol) multi-acrylate macromer (HB-PEG) with a series concentration of both components to form hydrogels. Rheology test were conducted at 37 °C to determine the gelation time and mechanical strength of the hydrogels. Hydrogel structure were observed under scanning electron microscopy (SEM) and in vitro hydrogel degradation were monitored for 28 days. Rat adipose derived stem cells (ADSCs) were encapsulated in hydrogels at a concentration of 1.0 × 10^7/mL. AlamarBlue® assay were applied at 1, 3, 7 days post-encapsulation and LIVE/DEAD® assays were used to determine the cell viability. Hydrogels with ADSCs were cultured in chondrogenesis medium for 28 days. Subsequently, RT-qPCR and histochemistry were conducted after 14 and 28 days to monitor chondrogenesis process.

RESULTS & DISCUSSION: Rheological analysis showed that the hydrogels formed in situ within 5 min and achieved a comparable mechanical strength as natural cartilage tissue. The hydrogels present an extra low degradation rate over a time scale of at least 28 days. ADSCs encapsulated in the regular porous scaffolds showed good cell viability over a period of 7 days. The enhanced chondrogenic differentiation were determined indicated by increased cartilage specific gene expression and ECM production. Significant increase (p < 0.001) of Sox9 at 14-days and Col 2a, ACAN 28-days post-encapsulation were recorded. The decrease expression of IL-1β exhibited no inflammation effect were induced by the hydrogel systems. Histochemistry intensity analyses demonstrated increased production of collagen type II at both 14- and 28-days post-encapsulation.

CONCLUSIONS: As indicated by the results, the functionalized CS based hydrogels serve as a stem cell delivery system that rapidly restores metabolism of encapsulated stem cells and promotes chondrogenesis. This tissue engineered injectable scaffolds hold promise for clinical translation in cartilage tissue regeneration.

In vitro cell assays and animal models are extensively used in early stage drug development for efficacy, risk and toxicity tests. However, these in vitro and in vivo models lack human physiologically relevance and therefore have limited predictive value of drug responses in humans. Three-dimensional (3D) tissue models are currently being developed as an alternative, more predictive assays for high throughput screening (HTS) for drug discovery. In this study, we have developed a novel bio-printed vascularized full-thickness skin equivalent (VFS) and a reconstructed human epidermis (RHE) in a multi-well plate format for the purpose of drug testing. The morphology and functionality of the skin tissue equivalents were confirmed with H&E staining, immunohistological characterization, and transepithelial electrical resistance (TEER) measurements. In the dermis of the VFS, confocal images of intact tissues stained with collagen IV and CD31 showed the 3D microvascular network and basement membrane of microvessels. Late epidermal differentiation markers illustrated that the epidermal layer was fully differentiated in both VFS and RHE tissues. Interleukin (IL)-4 treatment was used to induce atopic dermatitis (AD) like in the skin equivalents constructed. These AD models were able to reproduce several clinical hallmarks of AD including (i) spongiosis and hyperplasia; (ii) early and terminal expression of differentiation proteins; (iii) increases in levels of pro-inflammatory cytokines. Janus Kinase (JAK) inhibitors have been reported to be efficacious for the treatment of AD. The AD RHE was used to screen known JAK inhibitors and other compounds being tested for the treatment of AD in a 96-transwell format. Six effective JAK inhibitors from the primary screening were further tested in the AD VFS tissue model. The assay system for the AD VFS model includes tight junction barrier value, quantification of inflammatory cytokines, pro-angiogenic factors measurements and structural morphology changes in the microvasculature. In our study, we first provide an innovative and reproducible bio-printing biotechnology to create a vascularized human skin equivalent. Second, this construct combined with RHE is used in screening and developing pre-clinical drugs for skin disease. Third, endpoint readouts are quantifiable, robust, AD relevant, and can be scaled up to allow HTS for compound discovery. Thus, the skin equivalents developed in this study offers an in vitro approach for understanding pathological mechanism, efficacy of action and toxicity of dermal drugs.
Icariin protects annulus fibrosus cells in a rat model of intervertebral disc degeneration by MAPK signaling inhibition

INTRODUCTION: Icariin is the primary active ingredient of the herb Epimedium pubescens, a traditional Chinese medicine, which has been proved to be an alternative approach to treat bone-related diseases [1-3]. In the present study, the potential efficacy of icariin in protecting intervertebral disc was investigated using annulus fibrosus (AF) cells isolated from a rat model of intervertebral disc degeneration (IVDD).

METHODS: In total, 24 male 8-week-old Sprague-Dawley rats were used to develop a lumbar IVDD model. The differential expression of extracellular matrix in normal and degenerated rat AF tissues was observed using immunohistochemical and TUNEL staining. Isolated AF cells were treated with 0, 10⁻⁸ or 10⁻⁶ mol/l icariin as the IVDD group and the low- and high-concentration groups, respectively. The MTT assay was performed for cell viability, real-time polymerase chain reaction and immunocytochemistry for catabolic marker gene and protein expression and western blot for protein expression of mitogen-activated protein kinase (MAPK) signaling.

RESULTS & DISCUSSION: Degenerated AF tissues from the IVDD model at 8 weeks displayed increased collagen X and matrix metalloproteinase (MMP)-13 expression and cell apoptosis. Icariin treatment of isolated AF cells reversed the reduced proliferation induced by IVDD and significantly decreased catabolic marker gene and protein expression, including collagen X, MMP-13 and MMP-3. MAPK signaling was involved with the progress of IVDD in vitro. Furthermore, inhibition of MAPK phosphorylation, and thus activation, by icariin treatment reduced ERK, JNK and p38 protein expression in AF cells.

CONCLUSIONS: Our results suggest that icariin prevented intervertebral disc matrix degradation in vitro, and that acting as an MAPK inhibitor, it may be used as a potential therapy for the treatment of disc degeneration.

INTRODUCTION: According to the recent World Population Survey, there are approximately 1.66 million cases of articular cartilage damage worldwide each year and are increasing year by year. Tissue engineering is a means of repairing the integration of cells, biological materials and growth factors. The performance of tissue engineering materials largely determines the characteristics of the composite scaffold, so choosing the right materials and cells is especially critical. And the ideal scaffold should have a physiological layered.

METHODS: The control mixture was mixed according to Cs, GP, and Gel in a volume ratio of 3:1:2, 6:1:3.5, 9:1:5, 12:1:6.5, 15:1:8, 18:1:9.5. According to the principle of the connector, the mixture of the Cs/GP/Gel biomimetic gradient scaffolds was prepared by gradually diluting the concentration of the single layer mixture which is 0.15 mol/L. Rat bone marrow stem cells were seeded at 20,000 cells/cm² on Cs/GP/Gel biomimetic gradient scaffolds. SEM, water absorption, porosity, degradation rate, biocompatibility were conducted.

RESULTS & DISCUSSION: Cs/GP/Gel gradient hybrid scaffolds were successfully prepared in this study by controlling the concentration of monolayer solution, and the real physiological structure of natural cartilage was simulated. The scaffold had suitable water absorption (584.24±3.79 ~ 677.47±1.70%), porosity (86.34±5.10 ~ 95.20±2.86%) and degradation rate (86.09±2.46 ~ 92.48±3.86%). Staining showed that bone marrow mesenchymal stem cells had the ability to differentiate into bone and cartilage. BMSCs adhered and stretched well on this scaffold, which further confirmed its good biocompatibility.

CONCLUSIONS: The biomimetic gradient scaffold designed and prepared in this study provides an important basis for the development of new gradient composite biomedical materials and osteochondral repair.

INTRODUCTION: Cartilage can be tissue engineered from chondrocytes or from bone marrow derived mesenchymal stem cells (bMSC). Chondrocyte derived cartilage remains stable upon subcutaneous implantation whereas cartilage derived from bMSC transitions into bone via a process known as endochondral ossification (EO) [1]. The onset of EO is marked by the invasion by blood vessels in the cartilage [2]. We hypothesise that this process is induced by soluble factors secreted by hypertrophic chondrocytes. Here we compare the secretome of stable and transient cartilage for their effect on angiogenesis.

METHODS: Conditioned medium (CM) was derived from culture models for transient and stable cartilage [3]. As a model for transient cartilage we used 3D pellets of bone marrow derived mesenchymal stem cells (MSC) and as model for stable cartilage we used expanded primary articular chondrocytes. Three donors of each were differentiated over 21 days. [3] Pellets were characterized by histology and qPCR. The CM was used in different in vitro and in vivo/ex vivo assays: human endothelial cell migration and proliferation assays as well as a chick chorioallantoic membrane (CAM) assay and mouse metatarsal assay.

RESULTS & DISCUSSION: At the time of CM harvest chondrocytes and bMSC from all donors had deposited a matrix that stained positive for chondrocyte markers. Their gene expression mirrors this, whereas only the bMSCs expressed COL10A1 and ALPL. Both chondrocyte and MSC CM induced HUVEC migration, albeit the effect of MSC CM was significantly higher. Both CM stimulated proliferation of HUVECs and pro-angiogenic effects in both in vitro assay.

CONCLUSIONS: Secreted factors from engineered cartilage from both cell sources showed increased pro-angiogenic behavior in in vitro and in vivo angiogenesis assays. The migration assay reflected results of the metatarsal assay the most. Although both cell sources stimulated angiogenesis differently it is unclear if this can explain the difference in vessel ingrowth seen after in vivo implantation in mice. A physical rather than chemical barrier might be the explanation for this behaviour.

INTRODUCTION: Photothermal-chemotherapy is a promising synergistic cancer therapy due to high selectivity, and remote controllability [1] However, most of near-infrared (NIR) photothermal agent (PTAs) have challenges in the clinical translation due to their poor biodegradation and long-term toxicity [2]. Therefore, organism-based PTAs would be highly beneficial for clinical applications with excellent biocompatibility. Here, we proposed a photo-responsive system based on ascidian-inspired mussel adhesive protein (MAP) nanoparticles (NPs) for synergistic photothermal-chemotherapy.

METHODS: The catechol-metal complex-containing MAP NPs, and ammonium bicarbonate (ABC) and doxorubicin (DOX) co-loaded MAP NPs (MAP@ABC/DOX NPs) were fabricated by electrospraying. The real-time temperature of MAP NPs was detected by using a thermometer during exposure to an 808 nm laser. Next, human breast cancer cells MCF7 were incubated with MAP@ABC/DOX NPs and irradiated with laser for 2, 5, and 10 min respectively. After 24 h of incubation, the cell viability was evaluated by Cell Counting Kit-8 assay.

RESULTS & DISCUSSION: The MAP NPs successfully generated heat, elevating temperature of 60 °C upon laser irradiation for 10 min. In addition, MAP@ABC/DOX NPs efficiently released DOX upon laser irradiation through photothermal-induced generation of microbubbles from ABC. Next, the cytotoxic effects were investigated against MCF7 cells. The MAP NPs and MAP@ABC NPs showed negligible toxicity on the cells without laser exposure. Upon laser irradiation, the MAP NPs exhibited photocytotoxicity in an irradiation time-dependent manner and about 20 % of MCF7 cells remained alive after irradiation for 10 min. Compared to the photothermal therapy alone, less than 2% of MCF7 cells remained alive, demonstrating the synergistic efficacy of photothermal-chemotherapy.

CONCLUSIONS: The marine organism-based protein NPs had potential for clinical application of cancer-specific combined therapy with biocompatibility and high photocytotoxic effects.

Department of Materials Science and Engineering, National Tsing-Hua University, Hsinchu 30013, Taiwan, R. O. C.

INTRODUCTION: Timely tissue vascularization and integration of engineered tissues into a patient plays an important role in the successful translation of engineered tissues into clinically relevant therapies. To decrease the time needed to vascularize an engineered adipose tissue, suitable local microenvironments provided by hydrogels to support cell-based functional vascular network formation have been investigated. In this study, we compare the capability of engineering vascular network in vivo in different types of collagen and gelatin hydrogels, with controllable physical and chemical crosslinking. The relationships between vascular network formation and hydrogel properties for the hydrogels are discussed.

METHODS: Using the same biomolecule in solution, collagen and gelatin hydrogels with various crosslinking methods can be obtained. Human endothelial colony-forming cells (ECFCs) and mesenchymal stem cells (MSCs) were resuspended in pre-polymer solution and the mixture was implanted or injected into 6-week-old male nu/nu mice.

RESULTS & DISCUSSION: In order to demonstrate how and why physicochemical properties of collagen hydrogels regulate the extent of the ECFC-MSC based vascular network formation (Fig1a), the perfused functional lumen density and size, weight of engineered vascularized constructs, and percentage of human cells within the lumen were plotted against the hydrogel properties (G’, concentration of RGD and MMP, swelling, diffusion, mesh size, mesh density and in vivo biodegradation) and host immune response (murine leukocytes surrounding and inside the hydrogel constructs) of the self-assembled collagen hydrogels (physical, Fig1a), enzymatically cross-linked collagen-Ph hydrogels (chemical, Fig1a), and collagen hydrogels (i.e. no matter which crosslinking methods used, Fig1b). In physically cross-linked collagen hydrogels, the lumen density is proportional to the diffusion rate and number of infiltrating host leukocytes observed inside gels (data not shown). These results revealed that the extent of vascular network formation is highly dependent on the diffusion of gels and the number of infiltrating host leukocytes observed inside gels. On the other hand, in collagen-Ph hydrogels (data not shown), a higher diffusion and biodegradation rate of collagen-Ph hydrogels resulted in more infiltrating murine leukocytes inside gels, illustrating that these constructs have higher microvessel density and smaller lumens. Regardless of which cross-linking methods (Fig.1b) were used to polymerize collagen, the lumen density inside collagen gels is proportional to the diffusion property of gels and the degree of infiltration by murine leukocytes. Moreover, the weight and diameter of engineered collagen tissue constructs are highly proportional to the concentration of collagen instead of the crosslinking methods and stiffness.

CONCLUSIONS: These results show manipulating the polymerized methods of a hydrogel could not only modulate vascular network formation, but also regenerate adipose tissue in vivo.

INTRODUCTION: The fast corrosion rate and complex biological activities of Mg challenge its orthopedic application [1-3]. Here, we designed a composite coating Mg(OH)₂/SA/PTMC to improve corrosion resistance.

METHODS: There were three steps to prepare the composite coating. Hydrothermal method, immersion, and evaporation were used in this study. SEM, XRD, XPS, water contact angle and adhesion test were investigated to reveal the quality of the composite coating. Electrochemical corrosion test and immersion test in PBS were performed to evaluate degradation of materials in vitro. Rat bone mesenchymal stem cells (rBMSCs) cultured in sample extracts and surfaces were used to access cytocompatibility. Furthermore, samples were implanted into rat femur bone cavity, micro-CT was a technique to analysis degradation of materials in vivo and new bone formation around implants.

RESULTS & DISCUSSION: The thickness of PTMC layer and Mg(OH)₂&SA layer was 12.48 ± 0.70 μm and 10.58 ± 1.20 μm, respectively. With the linkage effect of SA, PTMC layer was adhered strongly onto Mg(OH)₂ layer without gaps. The electrochemical corrosion and 30-day immersion test results demonstrated high improvement of anti-corrosion properties in AZ31-OH&SA@PTMC compared with bare AZ31. Cell results suggested that AZ31-OH&SA@PTMC possessed better cell viability, adhesion and survival than bare substrates, indicating the composite coating had an excellent cell biocompatibility. Less volume loss and more new bone formation implied AZ31-OH&SA@PTMC could not only protect substrate from corrosion but also enhance bone formation in vivo.

CONCLUSIONS: A de novo designed sandwiched coating Mg(OH)₂/SA/PTMC was developed to modify Mg based biodegradable implants, paves a promising way for the development of fully biodegradable orthopedic implants.

Towards the production of a new animal model of tissue engineered vascular graft (TEVG): The production of CAM sheets from large animal skin fibroblasts

INTRODUCTION: Synthetic vascular grafts perform poorly in small diameter applications (<6 mm) with high risks of thrombosis and intimal hyperplasia. Our goal is to develop an entirely biological tissue-engineered vascular graft (TEVG) using Cell-Assembled extracellular Matrix (CAM). Large sheets of CAM were produced by cells in vitro, and then cut into yarns to be woven into TEVGs. The in vivo evaluation of a human CAM-based TEVG remains limited to immunodeficient or immunosuppressed animals, which are too small, too expensive, ethically challenging and/or too unstable for long-term studies. Consequently, a large animal TEVG is essential to evaluate the potential of the new approach in a clinically relevant setting (size and allogeneic). The goal of this study is the first step towards the production of a TEVG: the production of CAM sheets for a large animal model.

METHODS: Ovine, porcine, canine and human skin fibroblasts were cultured for two months in 6-well plates in DMEM/F-12 (1:1) medium supplemented with 20% of two selected serums (Biowest and Hyclone) alone or in combinations, antibiotics and 0.5 mM Na L-ascorbate. Perforation strength was measured with a spherical probe (95 mm diameter) at a rate of 20 mm/min. Large CAM sheets (10 x 18 cm) were cut using a custom device with blades that can cut ribbons with a uniform width between 1 and 20 mm. Yarn mechanical properties were studied with tensile tests (Shimadzu AGS-X 10kN) performed at a rate of 1% L0/s until break detection.

RESULTS & DISCUSSION: Serum alone greatly influenced the production of CAM sheets in a clearly species-dependent manner. Ovine emerged as the most promising species to produce CAM, although ovine sheets strength were almost four times weaker than that of human sheets (respectively 117±14 gf, n=5 and 424±76 gf, n=5). Ovine cells showed higher proliferation than human cells and produced less collagen. Also, serum concentration did not significantly change ovine sheet strength while it had a direct effect on human sheets. The addition of Insulin-Transferrin-Selenium to the culture medium slightly increased the ovine sheet strength (respectively 170±8 gf, n=5 and 161±26 gf, n=9, p>0.05). Larger ovine sheets, in T225 flasks, were produced and cut into yarns. Ovine yarns were weaker than their human counterparts when produced with the same width of sheet. An increase of the yarn width increased the strength at break of ovine yarns. Also, when yarns were twisted, their strength at break were increased.

CONCLUSIONS: An immediate solution to move forward in the production of TEVGs, would be to cut wider ovine yarns to obtain a similar strength than that of human yarns. This study demonstrated the important species-to-species variability in cell behavior, which becomes very apparent in long-term and complex culture systems.

ACKNOWLEDGEMENTS: Financial support was received from Initiative d’Excellence U. bordeaux (IdEx) (Senior Chair 2016-0389); Agence Nationale de la Recherche (ANR) (R16060 GG HumTex); ERC Advanced Grant (Human Textiles #785908)
INTRODUCTION: Impaired diabetic wound healing is associated with a dermal extracellular matrix (ECM) protein profile favoring proteolysis [1,2,3]. The ECM is an intricate network of various combinations of elastin, collagens, laminin, fibronectin, and proteoglycans that plays a key role in stimulating cell proliferation and differentiation [1]. Treatment of diabetic wounds with extracellular matrix sheet dressing material may be a promising source to improve wound healing.

METHODS: Using in vitro models of ECM sheet derived from human adipose tissue and in vivo diabetic murine wound healing models, we tested the hypothesis that ECM sheets enhance wound healing by decreasing proteolysis, hence enhanced re-epithelization rate and denser granulation tissue.

RESULTS & DISCUSSION: Microscopic analysis indicated that the re-epithelization rate of the wound was higher in the ECM sheet group compared to that in the control group (p < 0.001). Moreover, a denser and more organized collagen tissue was formed in the ECM sheet group compared to that in the control group (p < 0.001). The ECM sheet also showed the highest microvessel density compared to the control group.

CONCLUSIONS: These findings suggest a potential mechanism through which ECM sheet dressing enhance diabetic wound healing by improving collagen alignment and higher re-epithelization rate. We suggest that a bioactive ECM sheet dressing derived from human adipose can provide therapeutic proteins for wound healing in diabetic wound.

INTRODUCTION: Lactoferrin (LF) is a large glycoprotein that has been shown to have positive effects on bone. Previous in vivo work has shown that bovine LF, delivered in a collagen gel, increases bone formation in a rat calvarial defect model. Recombinant human bone morphogenetic protein-2 (rhBMP2) is a clinically approved growth factor for bone regeneration, and is delivered in an absorbable collagen sponge (INFUSE® Bone Graft kit, Medtronic). In this study, we used INFUSE® collagen sponges to deliver LF to rat calvarial bone defects, and compared the efficacy of LF in promoting bone regeneration to that of rhBMP2.

METHODS: Calvarial defects, five mm in diameter, were created over the left parietal bone in 30 Sprague–Dawley rats, which were randomised into three groups: i) empty defects (control), ii) defects grafted with LF/collagen sponge (100 ug/sponge), and iii) defects grafted with rhBMP2/collagen sponge (10 ug/sponge). Twelve weeks post-operation, calvariae were dissected and scanned by microCT (Skyscan 1172, Bruker). Bone volume (BV), tissue mineral density (TMD), porosity, volume, surface area and number of pores were compared between the groups. In addition, the calvariae in the rhBMP2 group were compared with intact calvariae from age-matched rats of the same strain. For histology, samples were fixed in 10% neutral buffered formalin, decalcified in 10% formic acid, paraffin embedded, and 10 µm thick slices were stained with haematoxylin and eosin.

RESULTS & DISCUSSION: There was no difference in the mean BV between the control and LF groups, whereas the BMP2 group had significantly higher mean BV than the control (p<0.0001) and LF (p<0.001) groups. The mean TMD was similar between all three groups. The BMP2 group had higher mean percentage of closed pores within the regenerated bone than the control (p<0.01) group, and higher mean volume of closed pores than the control (p<0.0001) and LF (p<0.001) groups. Histological analysis showed the presence of a fibrous-like structure within the regenerated calvariae of all rats treated with LF or rhBMP2, likely to be the collagen sponge still present at 12 weeks after operation. Also, all the calvariae in the rhBMP2 group had large cavities within the regenerated bone which were filled with blood cells and a large number of adipocytes. These large cavities and adipocytes were not present in the control and LF groups. Interestingly, reconstructed images from microCT suggested that BMP2-induced bone growth in excess of the normal thickness of the calvariae, when the rhBMP2 group was compared with age-matched calvariae.

CONCLUSIONS: LF delivered in INFUSE® collagen sponge had no effect on bone regeneration in this experiment, so further study is required to find a suitable delivery system for LF. BMP2 grafted in the collagen sponge improved bone regeneration, however, rhBMP2 induced excessive bone growth, which is generally not desirable in the clinical setting. Also, the regenerated bones had unusual features, including the presence of large cavities filled with numerous adipocytes, which might have a negative effect on bone health and strength. Therefore, although rhBMP2 promotes bone regeneration, there is still a need for further exploration of factors that might induce the formation of bone of better quality.
Differentiation of human amniotic fluid stem cells cultured on biomaterials having nanosegments

INTRODUCTION: Human amniotic fluid stem cells (hAFSCs) are pluripotent fetal cells, which are capable to differentiate into multiple lineages. However, when we are culturing hAFSCs, it takes a long time for hAFSCs to become confluence. Therefore, we designed a culture method of hAFSCs where the different substrates were coated on tissue culture polystyrene (TCPS) dishes, such as TCPS coated with Synthemax II (oligo-vitronectin based substrate), human recombinant-vitronectin (rVN), poly(N-isopropylacrylamide) (PolyNIPAAm) and poly(N-isopropylacrylamide-co-butylacrylate) (PolyNIPAAm-BA). Furthermore, we have investigated the differentiation ability of hAFSCs into multiple lineages such as osteoblasts, chondrocytes and retinal pigment epithelium cells. Thus, hAFSCs may become a more suitable source of stem cells in tissue engineering and regenerative medicine in future.

METHODS: We used different substrates coated on TCPS dishes. Especially polyNIPAAm or polyNIPAAM-BA were coated on cell culture dish conjugated with different ECMs (rVN) and Synthemax II. The optimal condition for hAFSCs attached on dishes by evaluating the doubling time was investigated. After the cells became confluence, the differentiation medium was introduced to induce the cells to differentiate into each cell lineage that we intended.

RESULTS & DISCUSSION: We found that hAFSCs had stronger adhesion on dishes which were coated with extracellular matrices such as rVN and Synthemax II than TCPS. Particularly, polyNIPAAm and polyNIPAAM-BA dishes coated with ECMs showed better cell proliferate ratio than conventional TCPS dishes. After the cells became confluence, hAFSCs differentiated into osteoblasts. At day 14, we detected the ALP (Alkaline Phosphatase) activity for the early stage of osteogenic differentiation. After day 28, we could evaluate the late stage of osteogenic differentiation by alizarin red S and von Kossa staining.

CONCLUSIONS: Our culture method shows that hAFSCs can grow faster than culture on conventional TCPS dishes and also has higher differentiation ratio on especially polyNIPAAm and polyNIPAAM-BA dishes coated with several ECMs. hAFSCs may become suitable source in tissue engineering and regenerative medicine in future.

INTRODUCTION: The cervix is one of the most important organs in the female reproductive system. But cervical cancer, induced by human papillomavirus (HPV) infection, has become the second death threat for women. Traditional treatment of cervical conization leads to partial tissue defect with significant pain points, and increases the risk of reproductive tract infection. More dangerous is leading to miscarriage and premature rupture of membranes [1]. In view of the worldwide cervical disease and the inevitable tissue damage caused by surgery, we aim at the engineering of implantable cervix constructs with drug-laden based on 3D printing technology.

METHODS: The proposed cervix construct was designed as a cone-shaped scaffold according to the excised tissue part in conization: 3000 μm in bottom diameter, 1500 μm in height with a hollow channel of 500 μm in diameter. Polyurethane (PU), a FDA-approved implantable material, was selected as the raw material for fabrication using low-temperature deposition manufacturing (LDM), with the concentration at 12.5% (w/v, PU/1,4-dioxane). Scaffolds with three different wire spacing (1000 μm, 1200 μm, 1500 μm) were printed to evaluate the effect of porosity on scaffold performance. Anti-HPV protein was loaded onto the porous scaffold through negative pressure. The biocompatibility, structural stability and protein release of the 3D printed PU-based structure was analyzed.

RESULTS & DISCUSSION: Tailored cervix construct was engineered by LDM followed with freeze drying process. The construct is a gradient porous structure with pore size varying from 1 to 100 μm. The elasticity modulus of PU is 11.75MPa and the elastic limit is 13.5%. The elongation at break is greater than 250%, which indicates that PU has good elasticity. The cytotoxicity test shows that HUVECs grow well in PU extract with a relative increase rate of 88%. Anti-HPV protein was successfully loaded into the pore structure, which endowed the construct protein sustained release functionality.

CONCLUSIONS: Implantable cervix constructs was designed according to the conization and fabricated using PU via the 3D printing technology of LDM. The characteristics of the gradient pore distribution facilitated the loading of anti-HPV protein into the constructs. The results of the biocompatibility, structural stability and protein release suggest the feasibility of current cervix constructs function as accurate, structured and tailored tissue elements as well as controlled-release drug delivery systems towards individual treatment.

INTRODUCTION: Human adipose-derived stem cells (hADSCs) exhibit heterogeneous characteristics, indicating various genotypes and differentiation abilities. The isolated hADSCs can possess different purity levels and divergent properties depending on the purification methods used. Hence, we developed a membrane migration method to isolate the hADSCs which can extensively reduce the purification time. Furthermore, the isolated hADSCs are expected to have high pluripotency and high differentiation ability into chondrocytes, osteoblasts, and adipocytes.

METHODS: We are developing a new membrane migration method using Nylon mesh membranes having optimal pore sizes, 11 and 20 μm, and PLGA/silk membranes where optimal extracellular matrix (ECM) is coated on the membranes, which can purify hADSCs. We isolated hADSCs from adipose tissue by the membrane migration method where different membranes are used, e.g., (a) Nylon mesh (pore size=11 or 20 μm) and PLGA/silk membrane, (b) Nylon mesh (pore size=11 or 20 μm) and PLGA/silk membrane coated with collagen type I, (c) Nylon mesh (pore size=11 or 20 μm) and PLGA/silk membrane coated with human recombinant-vitronectin, (d) Nylon mesh (pore size=11 or 20 μm) and PLGA/silk membrane coated with human fibronectin. Collagen type I is xeno-containing materials, other extracellular matrices (ECMs) are xeno-free materials.

RESULTS & DISCUSSION: hADSCs are successfully isolated by membrane migration method with different kind of membranes coated with extracellular matrices. After separating the hADSCs, we also counted the cell ratio of the isolated hADSCs (Fig. 1). Finally, the isolated hADSCs differentiated into osteoblasts. At 14 days, we detected the (alkaline phosphatase) ALP activity assay for the early stage of osteogenic differentiation. We also had the late stage of osteogenic differentiation detection with alizarin red and von Kossa staining after 14 days.

CONCLUSIONS: Membrane migration method can quickly purify and isolate the different types of hADSCs. In the late stage, migrated cells have the higher osteogenic differentiation ratio than those on TCPS (Fig. 2).

Figure 1: (Left) Cell ratio of the isolated hADSCs. Figure 2: (Right) Alizarin red staining ratio of the isolated hADSCs.

INTRODUCTION: For more safe and therapeutic effect of medical implants, their surface functionalization to enhance their regenerative performance is an effective approach. Especially with the medical implants for circulatory system, surface modification and its effect have critical effect. For the enhancement of regenerative effect on medical implants, our group have been exploring short peptides with cell-selective adhesion/growth [1,2]. These peptides are screened from combinatorial peptide library by evaluating the dual effect on different types of cells, which enhances the adhesion/growth of cells that enhance the regeneration and inhibits the cells with negative affect on implanted area. For the application of these peptides, we have been investigating bio-compatible scaffold material for medical applications. In this work, we have developed a hybrid material of polysaccharide and collagen processed by vitrification method [3]. We here report the mechanical property and its peptide-modified effect for evaluating its medical usage performance.

METHODS: Ten different types of polysaccharides were evaluated to make vitrified collagen hybrid film. Their mechanical properties and cell-selective adhesion performance was evaluated with endothelial cells, fibroblasts, and smooth muscle cells, which mainly consists of blood vessel and to be controlled in the regeneration of vascular tissue.

RESULTS & DISCUSSION: We found optimized condition of polysaccharide property together with the vitrification protocol and condition to maximize the cell-selective adhesion peptides. As a result, we found that our cell-selective peptides can provide cell-selective enhancement of endothelialization on newly designed polysaccharide and collagen hybrid material.

CONCLUSIONS: Our hybrid material combined with cell-selective material can serve as new regeneration enhancing material in medical usages.

INTRODUCTION: A variety of synthetic and natural biological materials have been used in the repair of peripheral nerve injury, and the surface properties are found to play an important role in tissue regeneration, however, it is still unclear about the effect of synergistic surface physical properties, especially for the elasticity and topography, on peripheral nerve regeneration.

METHODS: In this study, the chitosan/acrylamide hydrogel with different surface elasticity and topology was prepared by in-situ radical polymerization and micromolding methods. The physical and chemical properties of the hydrogel were characterized respectively. The effects of these materials on nerve regeneration are evaluated using dorsal root ganglion cell model, and the priority parameters for regulating cell growth were confirmed, including the morphology, number of protrusions and growth rate. Meanwhile, the transcriptome sequencing technology was employed to analyze the impact of the materials with different surface properties on the gene expression profiles. Moreover, the involved molecular mechanisms were also elucidated by the combination use of bioinformatics methods and experimental validation.

RESULTS & DISCUSSION: The results showed the chitosan/acrylamide hydrogel with different surface elasticity and topology could be well fabricated. The study reveals the structure-activity relationship between the growth of neurons and anterior horn motor neurons, respectively, yielded a range of favorable surface properties (elasticity and topology) for nerve regeneration.

CONCLUSIONS: The study demonstrates that the design of surface elasticity and topology of nerve implants will provide a potential and effective selection for biomaterials surface modification and shows great potential for the application in peripheral nerve regeneration.

Bilbao, Spain

INTRODUCTION: Regeneration of the nervous system is challenging due to its limited tissue plasticity and poor ability to regenerate after injury [1,2]. Stem cell-based therapies, even if promising, have faced important limitations in terms of cell survival and integration into the neural circuitry. To overcome this, we have developed two-dimensional nanostructured scaffolds based on bioresorbable polyesters and graphene oxide (GO) to promote the neurodifferentiation of dental pulp-derived stem cells (DPSCs).

METHODS: Poly (D, L-lactide) (PDLLA) scaffolds were first nanopatterned with grating of 350 nm linewidth and subsequently functionalized with polydopamine, which acted as an adlayer for the final immobilization of GO. Films were extensively characterized by means of scanning electron microscopy (SEM), atomic force microscopy, X-ray photoelectron spectroscopy and Raman spectroscopy. Human DPSCs were seeded on these films and after 1, 3 and 7 days, cells were fixed and immunostained for proliferation (Ki67), morphology (Rhodamine-Phalloidin), neuronal markers (NeuN, DCX) and glial markers (GFAP, S100b). Metabolic activity of cells was assessed using alamarBlue.

RESULTS & DISCUSSION: DPSCs adhere and proliferate in vitro on the developed scaffolds, as demonstrated by rhodamine-phalloidin and Ki67 immunostaining. Moreover, DPSCs were elongated and aligned in the nanograting axis. Immunohistochemistry analyses to cells incubated in Neurocult media show a higher expression of neuronal markers (i.e., NeuN and DCX) and a lower expression of the glial markers (i.e., GFAP and S100b) when seeded on nanostructured films functionalized with GO with respect to the control (i.e., flat surface without GO).

CONCLUSIONS: The combination of GO with nanoscale topographical cues provided by the polymeric structure would serve as functional mimics to drive neuronal commitment and directional growth of neurites, thereby enabling a simple and scalable method for a spatial alignment of DPSCs committed to neuronal fate for future clinical use.

INTRODUCTION: The treatment of chronic wounds represents a great challenge in Plastic and Reconstructive Surgery with limited options for efficient treatment. Hyperbaric oxygen therapy (HBOT) has gained interest as an experimental strategy to promote wound healing. HBOT means prolonged exposure to 100% O2 under increased atmospheric pressure (ATM). Mesenchymal stem cells (MSCs) play a major role in wound repair due to their multilineage differentiation capacity and paracrine function. In the present study, we studied the effect of HBOT on the biology of adipose tissue (AT-)MSCs in an in vitro setting.

METHODS: AT-MSCs from seven healthy donors were treated in a custom-made HBO chamber for five consecutive days with either 2 or 3 ATM. Metabolic activity was measured immediately before and after HBOT via PrestoBlue® staining. Proliferation was determined using Crystal violet staining. The effect of HBOT on adipogenic and chondrogenic differentiation was measured by Oil Red O and Alcian-PAS staining, respectively. Lastly, the secretion of cytokines in cell media was quantified by ELISA.

RESULTS & DISCUSSION: Treatment with 3 ATM enhanced metabolic activity 24 hours after treatment in a saw-tooth progress, and it increased proliferation over to the untreated control group and the 2 ATM treated cells. HBOT promoted adipogenic differentiation, while it did not affect chondrogenic differentiation. EGF, HGF and TNF-α were not detected in the cell supernatants, while secretion of TGF-β decreased 24 hours after the time points of the highest metabolic activity.

CONCLUSIONS: HBOT influences MSC metabolic activity and drives adipogenesis, supporting its effectiveness in the process of wound healing, especially in the field of soft tissue regeneration. However, 3 ATM seemed to be more effective than 2 ATM.

Figure 1: Metabolic activity measured with PrestoBlue® before (PB) and after (PA) each HBOT (1-5) for 3 ATM (right) and untreated control (left). Metabolic activity is increased 24 hours after treatment; note the zig-zag course for 3 ATM between PB and PA.

INTRODUCTION: Industrial-scale manufacture technologies for producing Mesenchymal Stem cells (MSCs) are expected to widely distribute cells for therapies [1, 2]. However, one of the bottlenecks is the quality monitoring difficulties for the stable and efficient cell manufacturing. By the lack of effective in-process measurement technology, cellular status monitoring during the total process of complex and long cell culture has been relied on manual microscopic observations. However, standardization and control of manual observation is difficult, and quantitative data understanding has been more difficult. To breakthrough such manual-based cell monitoring, we here propose the computational automatic concept to detect and visualize the irregular operation troubles that occur in the cell culture process only by the image-based cellular morphological information.

METHODS: Twenty-one lots of human mesenchymal stem cells (MSCs), were cultured under 5 conditions (one standard and 4 types of intentional errors, such as clear failure of handlings and machinery malfunctions). Using time-course images, cell morphological profiles were quantitatively measured and utilized for visualization and prediction modeling. For visualization, modified principal component analysis (PCA) was used. For prediction modeling, linear regression analysis and the MT method were applied.

RESULTS & DISCUSSION: By modified PCA visualization, the differences in cellular lots and culture conditions were illustrated as traits on a morphological transition line plot and found to be effective descriptors for discriminating the deviated samples in a real-time manner. In the prediction modeling, both the cell growth rate and error condition discrimination showed high accuracy (>80%), which required only 2 days of culture.

CONCLUSIONS: Morphological information that can be quantitatively acquired during cell culture has great potential as an in-process measurement tool for quality control in cell manufacturing processes.

INTRODUCTION: After severe trauma there can be significant nerve injury and loss of function in the nervous systems. Due to the various challenges in regeneration like slow axonal regeneration and inhibitory effects of injury environment, nerve recovery is one of the most complex biological phenomena [1]. This study presents preliminary results that focusing to nerve recovery by developing TiO2 phosphate glass fibers (PGFs) based bioprinted hydrogels.

METHODS: Phosphate glass fibers were produced (P2O5–CaCO3–NaH2PO4–TiO2) with the molar percentage of elements (0.5P2O5-0.35CaO-0.1Na2O-0.05TiO2). Cell line C6 (ATCC-CCL-107) rat glial cells were used at 5x10^5-6 cells/ml concentration. The hydrogel for 3D printing was GelMA and also preliminary results were obtained by using Type-1 Collagen gel. Cellink Inkredible™ 3D printer was used for bioprinting.

RESULTS & DISCUSSION: SEM, confocal microscopy and viability assessments (AlamarBlue) showed biocompatibility of PGFs and its directional guidance potential for growth of neural cells. Bioprintability of prepared GelMA hydrogels showed promising results regarding to cell viability and aligned growth after printing.

CONCLUSIONS: Thus far, data collected, together with expected results would be able to illustrate that PGFs with 3D printed GelMA may have a great potential to provide axonal regeneration for neural tissue engineering.

INTRODUCTION: Proper sustainable release of BMP needed for bone regeneration was reported to be decreased [1,2]. Compared to conventional hydroxyapatite, the nano-sized hydroxyapatite (nHAp) has superior osteoblast adhesion properties [3] and osteoinductive ability. Herein, we combined PLA-PEG with nHAp as carrier/scaffold system for BMP in order to investigate the bone regenerative capacity of newly established biomaterial in a rat spinal fusion model.

METHODS: BMP-2/PLA-PEG (5mg) /nHAp (12.5mg) composites containing different dosage of rhBMP-2 (0µg/3µg/10µg) were created. The release kinetics of rhBMP-2 from the composite was investigated by ELISA. For in vivo bone formation, same composites were placed on both sides L4-5 transverse processes and bone formation was assessed by μCT and histology at post-op. 8 weeks

RESULTS & DISCUSSION: The composite showed a burst-release (69% of the total release) in the initial 24 hours and the release was continued for 25 days. μCT and histology demonstrated that spinal fusion was achieved either one or both sides of the L4-5 transverse processes in all BMP3µg and BMP10µg groups (bilateral non-union / unilateral fusion / bilateral fusion, BMP0µg group; 10/0/0, BMP3µg group; 1/0/9, BMP10µg group; 0/1/7).

CONCLUSIONS: We developed a new biomaterial for bone regeneration with a novel composite of BMP-2/PLA-PEG/nHAp. The reduction in the required dosage of BMP-2 for 100% bony fusion in rat spinal fusion was achieved.

INTRODUCTION: Intervertebral disc (IVD) herniation causes low back pain, which leads to a high socioeconomic burden. Large annular rupture after discectomy is associated with an increased rate of reherniation. In this study a tissue engineered construct, composed of polyurethane (PU) scaffold with TGFβ supplemented type I collagen hydrogel and TGFβ pre-treated human AF cells, was evaluated in vitro and ex vivo for the repair of annulus fibrosus (AF) rupture.

METHODS: AF cells were isolated from human AF tissue of trauma patients, then expanded in αMEM with 10% FBS at 2% O2. In vitro, AF cells were cultured with or without 5 ng/ml TGFβ for 4 days, then evaluated by flow cytometry, gene expression analysis and cell contraction assay. TGFβ treated AF cells were seeded into PU scaffold only (PU-AFCs), or combined with collagen I hydrogel and treated with (PU-Col-AFCs-TGFβ) or without 5 ng TGFβ (PU-Col-AFCs). The cells were seeded into a PU scaffold (diameter 3.5 mm, length 4 mm) at a cell density of 0.2×10⁶ per scaffold. After 7 days culture, scaffolds were collected for gene expression and DNA and GAG content. Ex vivo, a bovine caudal IVD AF defect organ culture model created by biopsy punch (diameter 3 mm, length 4 mm) was used in this study. An acellular PU scaffold with collagen hydrogel (PU-Col), or PU-Col with TGFβ pre-treated AF cells with (PU-Col-AFCs-TGFβ) or without (PU-Col-AFCs) 5 ng TGFβ were implanted into annulotomized IVD for AF defect repair. After 14 days culture with physiological loading, discs were evaluated by Safranin O/Fast Green staining; implanted scaffolds were evaluated by gene expression.

RESULTS & DISCUSSION: In vitro, TGFβ treated AF cells had greater contractility, higher gene and protein expression of AF marker CD146, and higher SM22α and SCX gene expression compared with non-treated cells. When AF cells were seeded into PU scaffolds, gene expression of collagen type II, SM22α, SCX and MKX were increased while the metalloproteinase ADAMTS5 was decreased after 7 days culture in PU-Col-AFCs-TGFβ and PU-Col-AFCs groups compared with PU-AFCs group. Besides, higher DNA and GAG/DNA ratio were detected in PU-Col-AFCs-TGFβ group. Ex vivo, Implanted AF cells were present and started matrix production in both PU-Col-AFCs-TGFβ and PU-Col-AFCs groups after 14 days organ culture with physiological loading. However, PU-Col-AFCs-TGFβ group had greater cell number, collagen matrix production (Fig.1), and higher collagen I and CD146 gene expression.

CONCLUSIONS: TGFβ upregulated AF marker gene expression, and increased contractility in AF cells, indicating that TGFβ pre-treated cells may be a superior cell source for AF tissue engineering. Collagen type I hydrogel as a cell carrier in the PU scaffold maintained the functional phenotype. TGFβ treatment within the collagen hydrogel further promoted matrix production of AF cells both in vitro and ex vivo. PU-Col-AFCs-TGFβ constructs have a good potential for generating tissue engineered AF, and may therefore be used to repair AF defects after discectomy.

Poly(diol citrates) as versatile biomaterials: synthesis, surface properties and cytocompatibility studies
A. Flis¹, F. Koper², W. Kasprzyk², E. Pamuła¹
Presenting Author: Agata Flis, flis@agh.edu.pl
¹Department of Biomaterials and Composites, AGH University of Science and Technology, Kraków, Poland ²Faculty of Chemical Engineering & Technology, University of Technology, Kraków, Poland

INTRODUCTION: Poly(diol citrates) (PDC) are considered one of the most promising biomaterials for the fabrication of vascular tissue scaffolds. PDCs are thermoset and amorphous at 37°C and their mechanical properties and degradation kinetics can be adjusted. Moreover they are easy to synthesize, inexpensive and non-toxic [1]. By using various diols, the mechanical properties and degradation characteristics of the obtained PDCs can be tuned. The aim of this study was to synthesize poly(1,8-octanediol citrate)s of various molar ratios and to characterize their surface properties and cytocompatibility. These polymers, in our further studies, are intended to be modified with panthenol and/or glutathione to provide them with luminescent and antioxidative properties, what is relevant for vascular tissue engineering.

METHODS: Citric acid was reacted with 1,8-octanediol in molar ratio 1:1 and 2:3, creating poly(1,8-octanediol citrate). Reagents were added to 30-ml flask and melted at 140 °C for 40 min under stirring to synthesize prepolymer. Then, prepolymer were dissolved in ethanol, precipitated in water, lyophilized and post-polymerized for 2, 3, 4 or 5 days at 80°C. The surface roughness (Hommer-Werker profilometer) and the water and diodomethane contact angles of PDCs were measured by sessile drop method (DSA10, Kruss). The surface free energy was calculated by the Owens-Wendt equation. FTIR-ATR (Tensor 27, Bruker) analysis permitted to determine the surface chemical composition of the materials. Cytocompatibility studies with endothelial cells were tested in extracts from synthesized PDCs.

RESULTS & DISCUSSION: FTIR-ATR results show that PDCs with all studied molar ratios have similar spectra, differing only in peak intensities depending on composition. The samples were hydrophobic (water contact angle from 85° to 105°) and smooth (Rₐ in the range 0.16 - 0.40 µm). The surface free energy varied depending on polymer composition and post-polymerization time. Metabolic activity of endothelial cells cultured in the extracts from PDCs was not significantly different as compared to cells cultured in control conditions.

CONCLUSIONS: Two PDCs with different molar ratio were synthesized and their surface properties were characterized. They were found cytocompatible with endothelial cells, what paves the way of their further application in vascular tissue engineering.

INTRODUCTION: Glaucoma is the second-leading cause of blindness with patient numbers to reach 80 million by 2020. There is no cure for glaucoma and progression often leads to intervention via trabeculectomy. Unfortunately, 30%–50% of these procedures fail due to formation of post-operative fibrotic fistulas [1, 2]. The formation of these fistulas is known to follow a two-stage process with inflammation and angiogenesis over the first 1-7 days followed collagen deposition over a 4-week period [3].

METHODS: To target these events, a modified hyaluronic acid (HyA) hydrogel was developed capable of controlled anti-inflammatory/fibrotic drug release profiles. Modified hydrogels were assessed for changes in mechanical strength, degradation and ease of insertion into cadaveric sheep eyes. Furthermore, anti-inflammatory/anti-fibrotic drug release was assessed using cell culture and a chick embryo model of angiogenesis.

RESULTS & DISCUSSION: On analysis, it was found that HyA hydrogels were capable of rapid swelling (<30 min) and were stable in physiological conditions up to a minimum of 8 weeks but demonstrated dose dependent enzymatic degradation. Secondary modification allowed for an immediate anti-fibrotic effect through a 50% drop in collagen deposition in vitro at 24hrs. Furthermore, drug-loaded gels demonstrated visible decreases in angiogenesis up to day 7.

CONCLUSIONS: This work demonstrates a highly controllable hydrogel matrix capable of contact inhibition and anti-fibrotic drug release. It is now expected to be assessed in in vivo glaucoma models.

ACKNOWLEDGEMENTS: This work was funded by Science Foundation Ireland through the TIDA award 17/TIDA/5098.

INTRODUCTION: Hydrogels represent versatile 3D biomimetic cell culture matrices, with their mechanical properties influencing proliferation, migration and differentiation of stem cells. In this study, we investigated how the stiffness of methacrylamide-modified gelatin (Gel-MOD) hydrogels affects proliferation and differentiation of immortalized human adipose-derived stem cell (hASC/hTERT) microspheroids in control (Ctr), chondrogenic (Ch) and osteogenic (Ost) medium.

METHODS: Microspheroids containing 1000 (hASC/hTERT) were produced employing MicroTissues® 3D Petri Dishes® (Sigma) and re-suspended in control medium containing 5, 7.5 or 10% (wt%) Gel-MOD and 0.6 mM photoinitiator. Volumes of 30μL (containing 81 microspheroids) were dispensed on pre-methacrylated glass-bottom dishes and crosslinked by exposure to UV-A light (10 min at 365 nm and 25 mW/cm²). After 3 – 5 weeks of culture in Ctr, Ch or Ost media, cell viability, gene expression, matrix production or mineralization were monitored using confocal microscopy (Live/Dead staining), quantitative polymerase chain reaction and histological analyses, respectively. The stiffness of 1mm thick Gel-MOD sheets was determined by rheology.

RESULTS & DISCUSSION: Regardless of the medium used, cells in microspheroids remained viable for 3-5 weeks in all hydrogels. Ctr medium supported fast sprouting and inter-connection of cells in softer hydrogels, which was slower and very limited in Ost and Ch media, respectively. High expressions of SOX9, COL2A1 and ACAN and a positive Alcian blue glycosaminoglycan staining were detected in all tested hydrogels, cultured in Ch medium. Although expressions of RUNX2, ALPL, BGLAP and COL1A1 were not conclusive in the samples subjected to Ost medium, Von Kossa staining showed a strong calcium presence in the two softer hydrogels. The storage modulus G’ of investigated formulations 5, 7.5 and 10% Gel-MOD concentrations corresponded to 538, 3584 and 7263 Pa, respectively.

CONCLUSIONS: In the presence of a corresponding differentiation medium, Gel-MOD hydrogels support moderate osteogenic and excellent chondrogenic differentiation of encapsulated hASC/hTERT microspheroids, the extent of which depends on hydrogel stiffness. The hydrogel-microspheroid strategy proved exceptionally successful in promoting chondrogenesis, which was confirmed at the gene and protein levels.

INTRODUCTION: Nitric oxide facilitates wound healing and protects the wounds from bacterial infection. The treatment of wounds with gaseous NO and/or with NO donors was shown to be effective [1, 2]. The aim of our research was to study the effects of gaseous nitric oxide (Plason device) and low-molecular dinitrosyl iron complexes (DNIC) with thiol ligands (cysteine or glutathione).

METHODS: Experiments were performed in 40 male albino rats (August, 120–140 g) kept under standard conditions. A circle of 8–10 mm diameter was excised down to the fascia from depilated skin between the shoulder blades of the animals. There were 2 groups of 20 animals. In the study with the nitric oxide donors (group 1), there were 4 subgroups of 5 animals. The injections were on the first and the second day after surgery. In the 1st subgroup (control) 0.6 ml of saline was syringed once a day; in the 2nd subgroup: DNIC-Cys 5 μmol; in the 3d: DNIC-GS (2.5 μmol), total 5 μmol; in the 4th: S-nitrosothiol (GSNO) (5 μmol), total 10 μmol. In the study with gaseous nitric oxide (group 2), in the 1st subgroup (control), the wounds were left without treatment. In the 2 subgroup the temperature of NO-containing gas flow (CGF) (tNO-CGF) was 60°, NO containing (NOc) – 560 ppm; in the 3rd one tNO-CGF was 22°, NOc – 560 ppm; in the 4th one - tNO-CGF was 22°, NOc – 1120 ppm during 90 seconds on Day 1, Day 2 and Day 3 after surgery. On Day 4 the animals were removed from the experiment and wound tissues were analyzed with morphological, immunohistochemical, morphometric and statistical methods.

RESULTS & DISCUSSION: Histological data showed that dimeric DNIC with cysteine or glutathione were beneficial for wound healing at optimal amounts (cumulative 5 μmol per wound). Application of DNIC reduces inflammation and facilitates the growth and maturation of the granulation tissue. However, the same amount of NO with GSNO (10 μmol) worsened the condition of the wound. In all the experimental subgroups the study of the gaseous nitric oxide demonstrated that the intensity of inflammation was statistically lower and the ratio of regeneration (vascularization, fibroblast proliferation, synthesis and fibrillogenesis of collagen) was statistically higher than in control one. The effect was more expressed in the 4th subgroup with a two-fold increase in the content of nitric oxide at the distance of l=65mm. According to the morphometric study, the application of the NO-CGF at l=130 mm led to a thinner layer of fibrin and at l=65 mm – to the increase in content of collagen types I and III. The temperature factor of the NO-CGF did not affect the course wound healing.

CONCLUSIONS: Application of NO-CGF and NO-donors demonstrated beneficial effect on microcirculation, induction of phagocytosis, angiogenesis, proliferation of fibroblasts and activation of antioxidant protection through oxidative stress. The application of NO reduced inflammation and stimulated regeneration in wounds.

INTRODUCTION: Endothelial progenitor cells (EPC) as well as mesenchymal stem cells (MSC) produce a number of biologically active substances secreted in a form of microvesicles (MVs). Microvesicles transfer and release their cargo; thus changing microenvironment in a way that could promote regenerative processes.

METHODS: MVs were isolated from human EPC cell line HEPC-CB.1 and human MSC cell line HATMSC1 using a serial centrifugation method. The protein content of MVs was examined using Human Angiogenesis Array C1000 (RayBiotech). The presence of hypoxia- and angiomiRs in MVs was investigated in real-time RT-PCR with TaqMan technique. Cell proliferation (human microvascular dermal endothelial cell line HSkMEC.2, human fibroblast cell line MSU-1.1 and human keratinocyte cell line HaCaT) was investigated using the standard MTT test. Angiogenic properties of MVs were examined in Matrigel angiogenic assay with the use of HSkMEC.2 cell line.

RESULTS & DISCUSSION: MVs of EPC expressed 28 proteins, and MVs of AT-MSC expressed 12 proteins among 43 examined. Both EPC and MSC MVs transport growth factors (e.g. bFGF, EGF) and proangiogenic factors (e.g. IL-8, VEGF, TIMP-1, TIMP2). MVs isolated both from EPC and MSC are enriched in all examined miRNA such as: miR 210, miR 296, miR 126 and miR 378 as compared to the parental cells. The effect of isolated MVs on the proliferation and angiogenic properties of the cells involved in wound healing was examined. Both EPC and MSC derived MVs increased proliferation of human endothelial cells and this effect was dose-dependent. MVs also improved angiogenic properties of endothelial cells in a dose-dependent manner. Pseudotubule formation was visible only for a ratio of 100:1 (100 MVs per 1 cell), not for the ratio of 10:1. The effect was observed for MVs of both EPC and MSC origin (Fig.1).

CONCLUSIONS: This result suggests that MVs released by mesenchymal stem and endothelial progenitor cells influence biological activity of endothelial cells in the wound microenvironment.

Figure 1: Pseudovessels creation. HSkMEC.2 cells were incubated 24 h in the presence of MVs from HEPC-CB.1 or HATMSC1 cell lines, at a ratios of 10:1 and 100:1. Picture acquisition in an Olympus CKX41 microscope, magnification 40x.

INTRODUCTION: Mesenchymal stem cells (MSCs) are one of the most promising tools for regenerative medicine. The “gold standard” in the cell-based treatment of damaged tissues is the direct transplantation of cells, but tracking them and keeping in one particular place of injured organ is difficult. This problem could be solved by application of MSC attached to 3D scaffolds. We investigated the biological properties and osteogenic potential of sheep bone marrow-derived MSCs (BM-MSCs) and efficacy to seed them onto biocompatible scaffold.

METHODS: Bone marrow (8-10ml) was collected from sheep iliac crest (n=6). Flow cytometry for stem cell markers expression was performed on a BD FACS Calibur. MSCs differentiation into the osteogenic lineage in dedicated medium (PromoCell) was followed by Alizarin Red S, anti-osteocalcin, anti-collagen type I immunofluorescence staining, and osteopontin (OPN) gene expression by PCR. Cells were seeded at the density 1x10⁶/ml medium onto a polymeric scaffold. The deposition and morphology of sheep MSCs growth on the 3D scaffold was examined on day 3, 7 and 12 by PKH26 Red and DAPI staining.

RESULTS & DISCUSSION: Sheep bone BM-MSCs were positive for CD73, CD90 and CD105 and negative for hematopoietic markers CD34, CD45 and MHC class II. Cells incubated in osteogenic medium for 21 days exert bone mineralization capacity confirmed by Alizarin Red S staining. Moreover, the osteogenic markers: osteocalcin and type I collagen were detected by immunofluorescence and OPN by PCR.

CONCLUSIONS: Sheep BM-MSCs with characteristic naïve stem cell markers expression, were able to differentiate into osteogenic lineage and to proliferate on 3D scaffold. Thus, sheep bone marrow may be use as a potential source of MSCs for the studies of bone regeneration and the sheep can serve as a large animal preclinical model for bone engineering.

Figure 1: Immunofluorescence staining of collagen I and osteocalcin after 21 days of differentiation. Sheep MSC were seeded onto biocompatible 3D-scaffold to construct bioengineered bone. The deposition, morphogenetic and viability of seeded cells were determined by PKH26 Red and DAPI staining. After 12 days of culture, BM-MSC were attached and spread well on the scaffold. PKH26 (red) and DAPI staining sheep MSCs attached on the 3D scaffold after 12 days of incubation.

INTRODUCTION: Breast cancer (BC) is one of the leading causes of death worldwide. Available models to study estrogen receptor α (ER)-positive BC and to evaluate drug response fail in recapitulating specific disease features, such as the ER signaling [1]. Herein, we propose a 3D ex vivo patient-derived model of ER+ BC based on alginate encapsulation and orbital-shaking, previously validated in our group for cell lines [2,3]. This strategy allows cellular crosstalk, retention of ECM components and promotes uniform distribution of both nutrients and cell-secreted factors.

METHODS: >80 tumor samples were collected during surgery and transported to the laboratory within 4 hours, where they were mechanically dissociated, digested and encapsulated with 2% alginate. Encapsulated explant cultures were kept under orbital shaking. Cell viability was assessed along culture, using fluorescein diacetate (FDA) and propidium iodide (PI) to stain live and dead cells, respectively. Encapsulated explants were collected after 1 month in culture and paraffin blocks were prepared and sectioned for immunohistochemistry and hematoxylin and eosin (H&E) staining. To assess ER presence and functionality, explant cultures were challenged at day 30 with estradiol, a natural ER agonist, and the expression of downstream effector genes evaluated by RT-qPCR.

RESULTS & DISCUSSION: Alginate encapsulation and dynamic culture conditions showed to be an efficient strategy for long-term maintenance of breast cancer explants with high cell viability and retention of tissue architecture, including epithelial and stromal phenotypes and ratios. Importantly, after 1 month in culture, ER protein was still detected in the explants. ER functionality was demonstrated by an increase in the expression of downstream effectors of ER signaling (progesterone receptor: PR; amphiregulin: AREG; trefoil factor 1: PS2) upon stimulation.

CONCLUSIONS: Here we propose a new tissue-based 3D ex vivo cell model suitable for studying and interrogating ER signaling and evaluation of ER targeted compounds.

INTRODUCTION: Osteoarthritis is characterized clinically by pain and a progressive decrease in joint mobility. The implantation of synovial membrane mesenchymal stem cells (MSC\textsubscript{SM}) has shown promising results for its treatment. The challenge of the technique is to keep the cells at the site of action to increase their therapeutic potential \cite{1}. The aim of this study was to evaluate the effectiveness of the Qtracker\textsuperscript{®} 655 nanocrystal marking on allogeneic MSC\textsubscript{SM}, encapsulated in alginate hydrogel, evaluating the migration of these cells to the synovial joint.

METHODS: Five horses were submitted to arthroscopic surgery (D0), chondral lesion was induced in the radial carpal bone of both thoracic limbs. The 10 radiocarpal joints were divided into two groups (GA, GB). The chondral defect was treated according to the group: GA received free-labelled MSC\textsubscript{SM} and GB received labelled MSC\textsubscript{SM} microcapsules\cite{2}. Seven days after lesion induction and implantation of labelled cells, biopsies of the lesion site were performed in two animals, and fragments of SM and joint capsule were collected, which were frozen and later processed in histological sections for fluorescence microscopy visualization. The synovial fluid of the other three animals was analyzed by flow cytometry three times – 3, 7 and 21 days after application.

RESULTS & DISCUSSION: The viability obtained prior to cell labelling was 90 ± 2% and after incubation (24 hours) with the Qtracker 655 nanocrystal \cite{2} continued with 90 ± 2.5%. The cellular marking with the nanocrystals allowed the visualization of the cells in cartilage, synovial membrane, synovial fluid and articular capsule, but with a predilection for the synovial membrane. Flow cytometry of synovial fluid was also used to evaluate the migration of MSC\textsubscript{SM}, where we observed that the cells survived and remained marked for up to 21 days. The labelled MSC\textsubscript{SM} inserted in microcapsules were scarce in the synovial fluid and could be related to the small quantity of MSCs leaving the pores of the microcapsules, since the MSCs of horses have a mean diameter of 19.8 and 20.4 μm, derived from marrow bone and umbilical cord, respectively.

CONCLUSIONS: The MSC\textsubscript{SM} labelled with the Qtracker 655\textsuperscript{®} nanocrystals did not show a decrease in their viability in the in vitro analyses, suggesting that the nanocrystal is safe and has no toxic effect on the cells. There was an evident presence of marked cells in the synovial membrane and the observation of these cells at the lesion site was scarce. Cells encapsulated in less quantity are also favorable, because the cells release paracrine effects acting for a long period until differentiation.

INTRODUCTION: Damaged cartilage does not heal easily because of low intrinsic regenerative capacity and vascularization of cartilaginous tissue. Stem cell tissue engineering is an advantageous treatment strategy, but optimal cell sources and cell expansion as well as production of a functionally similar construct, that is ideally able to seamlessly integrate into the existing tissue, all pose challenges. Most current strategies use scaffolds to regulate construct properties with cells seeded on them. However, within cartilage, extracellular matrix (ECM) is responsible for its unique mechanical properties, and in that aspect scaffold-free approach, where cell aggregates are used as bio-ink, also relies on the produced ECM. Both approaches aim at eventual integration of construct into damaged tissue. Cartilaginous tissue functions under constant dynamic load, and uniformity of mechanical properties across the repaired cartilage surface is crucial for equal load distribution and therefore must have uniform resistance and elasticity. This study evaluated mechanical properties and ECM production in spheroids of differentiating chondro-progenitors.

METHODS: Human MSCs were derived from Wharton’s jelly, dental pulp, and adipose tissue. Primary chondrocyte culture served as positive control. Cells were first expanded as a 2D culture in DMEM/F12+10%FBS, then spheroids of each cell type were formed by aggregation of 8,000 cells per well in a 96-well ULA plate in 100 ul of the growth medium replaced by chondrogenic medium after 24 h. Spheroid fusion was initiated on days 1, 7 and 14 by placing two spheroids into one well. Spheroid formation and fusion were monitored using IncuCyte Live Cell Analysis System. The MicroSquisher was used to measure Young modulus of spheroids every three days for two weeks. ECM production in spheroids was evaluated by using alcian blue and Masson’s trichrome staining after 14 days of incubation in chondrogenic medium.

RESULTS & DISCUSSION: Elasticity modulus of spheroids of chondrogenically differentiating MSCs was increasing compared to spheroids of control MSCs and was similar to that of chondrocyte spheroids. It also positively correlated with glycosaminoglycan and collagen production (higher levels observed in spheroids of adipose tissue-derived MSCs). Spheroid fusion initiated on days 7 and 14 after differentiation induction was impaired, but control spheroids of all the cell types tested fused equally well at all time points.

CONCLUSIONS: Young modulus together with molecular marker levels is a useful indicator for assessing ECM formation and construct applicability. Spheroid fusion is adversely affected by cell differentiation. Nevertheless, the results indicate that spheroids of chondro-differentiated MSCs are potentially suitable for building tissue constructs for treatment of damaged cartilage.

INTRODUCTION: The Z-disc streaming is a feature of defect in cytoskeletal muscles, where the Z-disc in the sarcomeres is fragmented or localized to become confused. In our col4a1 mutants, the Z-disc streaming rate was observed as a result of increased temperature.

METHODS: Common oviducts were removed under carbon dioxide anesthesia from adults that were grown at both permissive and restrictive temperature for 14 days. Dissected common oviducts were fixed in 4% paraformaldehyde dissolved in phosphate buffered saline (PBS) for 10 min, washed three times in PBS, permeabilized for 5 min in 0.1% Triton X dissolved in PBS and washed three times in PBS. Blocking was achieved for in 5% BSA dissolved in PBS for 1 hour, and washed three times in PBS.

RESULTS & DISCUSSION: In order to determine the exact position of the Z-discs in the muscle fibers of the oviduct, we used antibodies against the scaffold protein kettin as a morphological marker. Immunohistochemistry using anti-integrin antibodies provided the same staining pattern in close localization as observed for kettin, confirming integrin localization to the Z-discs in muscle fibers of the oviduct. In col4a1 mutant, we observed aberrant integrin expression in the epithelial cells of the Malpighian tubules, and also surmised irregular integrin deposition in muscle fibers, consistent with the muscle pathology of Z-disc streaming.

CONCLUSIONS: The disrupted sarcomeric cytoarchitecture, Z-disc streaming collectively suggest a role of COL4A1 in integrin mediated adhesion. In conclusion, our Drosophila mutant series may serve as an effective model to uncover the mechanisms by which COL4A1 mutations result in disrupted myofiber-basement membrane interactions and improper muscle function.

Presenting Author: Andrea Schwab, andrea.schwab@aofoundation.org

¹AO Research Institute, AO Foundation, Davos Platz, Switzerland

INTRODUCTION: 3D (bio-) printing is an additive manufacturing method to fabricate structured, multi-layered hybrid scaffolds that mimic zonal orientation of extracellular matrix. Here, tyramie modified hyaluronic acid (THA) was combined with collagen I to investigate cell instructive properties for application in 3D printing of anisotropic cartilage scaffolds.

METHODS: THA (2.5% w/v) hydrogels were prepared via enzymatic cross-linking using horseradish peroxidase (0.3 – 1.0 U/ml) and hydrogen peroxidase [1]. Composite hydrogels were prepared by functionalizing THA with acidic dissolved collagen I (0.5% w/v), isolated from rat tail, in equal volumes of both precursor gels (THA-col). Structural organization of collagen I in composite hydrogels were evaluated by turbidity measurement (313 nm) over 60 min at 37°C and via polarized light microscopy of cryo-sections. Cell attachment on THA and THA-col was evaluated after seeding with bone marrow derived hMSCs by life-dead staining. To evaluate cell behavior, hMSCs were encapsulated in THA-col and cultured up to 21 days. Immune histochemistry, GAG and DNA assay as well as viability assay were conducted over time.

RESULTS & DISCUSSION: Turbidity measurement resulted in the presence of collagen fibers correlating to increase in absorbance. The presence of thin collagen fibers within the double network hydrogels were visualized by polarized light microscopy and confirmed by immune histological staining for collagen I. DN hydrogels induced hMSC attachment and spreading. For cell encapsulation similar trend was observed: Cells were spindle shaped and attached to THA-col within 1 day whereas MSCs stayed round and did not attach in THA gel.

CONCLUSIONS: THA with its property to adhere to cartilage ECM can overcome the limited integration of scaffolds in cartilage repair. Combining collagen and THA results in cell instructive properties by means of cell adhesion and spreading since collagen naturally contains cell adhesion ligand RGD [2]. Whether anisotropic properties of this biomaterial ink induce cell alignment, migration and cell differentiation is going to be evaluated.

INTRODUCTION: In vitro 3D-engineered bone marrow microenvironment based on human mesenchymal stromal cells (hMSCs) has been shown to successfully maintain functional human hematopoietic stem and progenitor cells (HSPCs) (1). However, the availability and variability of hMSC material remain as major limitations to go further in the in vitro HSPCs expansion challenge. We now propose to substitute primary hMSCs by an immortalized cell line exhibiting MSC properties (MSOD) (2) to generate a standardized hematopoietic stem cell niche.

METHODS: 10^6 hMSCs were seeded and cultured within collagen scaffolds (Ultrafoam, 8 x 4 mm) under direct perfusion flow. After 3 weeks of culture in osteogenic medium, the resulting microenvironment was seeded with either cord blood-derived or buffy coat-derived CD34+ cells and cultured for 1 week. The capacity of the MSOD engineered niche to maintain HSPCs was assessed by flow-cytometry (CD34 CD38 CD45RA CD90 markers), while their functionality was evaluated with Colony Formation Unit Assays (CFU-Cs).

RESULTS & DISCUSSION: Contrasting the 60% of hematopoietic cells that could be retrieved from hMSCs-derived engineered niches, only 7% of cord blood-derived cells and 3% of buffy coat-derived cells could be recovered from niches engineered with MSOD cells. Furthermore, less than 5% of these blood cells remained in the engineered niche (the vast majority of them were retrieved from the supernatant fraction). Intriguingly, MSOD cells exhibited a 8.7-fold expansion during the culture, while our previous results showed that primary hMSCs presented only a 1.7-fold expansion. MSOD niches did not expand primitive HSCs (CD34⁺CD38⁻) in comparison with unseeded collagen scaffolds, but promoted a 2-fold expansion on more committed hematopoietic progenitors (CD34⁺CD38⁺ and CD34⁺CD38⁺). Furthermore, in vitro CFU-C assays revealed that cord blood-derived and buffy coat-derived HSPCs cultured in MSOD niches maintain their differentiation properties since they could give rise to more committed progenitors (CFU-GEMM, CFU-GM and BFU-E).

CONCLUSIONS: The use of MSOD cell line allows the standardization of engineered hematopoietic stem cell niches, which promote HSPC expansion and differentiation. However, its efficiency to host hematopoietic cells is dramatically reduced in comparison with hMSC-derived niches. The massive expansion of MSOD cell counts during the culture might suggest an uncontrolled MSOD proliferation, which eventually could saturate the niches and impair HSPC maintenance. Therefore, in order to improve their functionality, engineering MSOD niches require further research to readjust culture settings according to MSOD proliferation.

Piezoelectric polymeric nanofibers as smart scaffolds for tissue engineering
A. Zaszczyńska, P. Ł. Sajkiewicz, A. Gradyś
Presenting Author: Angelika Zaszczyńska, azasz@ippt.pan.pl
1Institute of Fundamental Technological Research Polish Academy of Sciences, Laboratory of Polymers and Biomaterials, Warsaw, Poland

INTRODUCTION: As regards the field of biomedical engineering, in recent decades there is observed an increasing scientific and technical interest in research related to development of Smart Materials (SM). Such materials are generally designed to react to external stimuli (physical, chemical, mechanical) and behave similarly to natural body tissues. One type of such SM are piezoelectric scaffolds, which can generate electrical signals in response to the applied stress [1,2].

METHODS: Polyvinylidene fluoride (PVDF) nanofibers formed by electrospinning were subjected to in-vitro cellular studies. In the stimulation experiments, fibroblasts L929 cells cultured on the piezoelectric PVDF scaffolds collected at various rotational speeds of the collector, were exposed to ultrasounds for 30 minutes, one time per day, for 7 days. Ultrasound stimulus with power 20mW, 80mW and frequency 1,7 MHz were applied. In order to confirm the piezoelectric effect of the PVDF scaffolds on fibroblasts activities, piezoelectric PVDF scaffolds without ultrasonic stimulation were used as a control.

RESULTS & DISCUSSION: Enhanced viability and activity of cells dynamic culture have been observed and are invoked as a proof of suitability of the piezoelectric effect (Fig. 1). Cell culture studies demonstrated that the viability and growth of fibroblasts on PVDF fiber scaffolds were comparable over a 7-day period. The observations using SEM verified the attachment and proliferation of the cells on the fiber scaffolds. Moreover, the cell morphology on the fiber scaffolds was different when the 1-day culture and 7-day culture images were compared: on day 1, the cells had more rounded morphology while for 7 days their morphology was more elongated and spread-out (Fig. 1).

CONCLUSIONS: The use of ultrasounds stimulation, in combination with piezoelectric polymers, is advantageous for cellular studies. Exhibiting good cellular response show potential to be used in tissue engineering as a scaffold material.

Figure 1: Viability of fibroblasts L929 using ultrasound stimulation with different power. SEM images of PVDF nanofibers with fibroblasts L929 cell culture on day 7.

INTRODUCTION: Bone screws are a standard technique to stabilize bone fragments in orthopaedic fracture repair. The risk of screw loosening may be reduced by augmenting the fixation with self-setting calcium phosphate cements, however in the fractured femoral neck these impair healing [1]. A non-setting mix of a gel and hydroxyapatite (HA) has, on the other hand, been reported to result in rapid mineralization in vivo [2]. More recently it has also been shown that a non-setting gel-HA combination increased screw pull-out strength in cancellous bone granting instant grip [3]. The present study aims to further explore this unexpected reinforcing effect arising from particulate fillers in hydrogel matrices, and investigate a possible optimization of their particle size as enhancement of this bone augmentation.

METHODS: Gels consisting of 2% w/v agar in calcium-free PBS were used as base material and compared to 40%w/v hydroxyapatite (HA) reinforced gels. Two different HA sizes were used, varying by one order of magnitude (3µm to 300nm, denoted mHA and nHA, respectively). Strain and frequency sweeps were used to determine the viscoelastic properties of the gels (37°C, parallel 19mm Ti plate, 650µm gap). Screw pull-out tests were performed using cancellous titanium screws inserted 10mm (HB 4x16mm) in femoral condyle rabbit bones as previously described [3].

RESULTS & DISCUSSION: All materials showed a steady solid-like behavior (G’>G’’) and presented a linear behavior up to 0.5% strain from the strain sweep tests. Frequency sweeps depicted a clear nHA reinforcement with higher values for both G’ and G’’ moduli (4.5·10^5 and 1·10^5 Pa, respectively) compared to agar (8·10^3 and 1·10^3 Pa, respectively) and agar with mHA (2·10^5 and 6·10^4 Pa, respectively) relating to an increase in particle-gel interactions. The pull-out forces correlated with this reinforcing effect derived from the rheological evaluation, which might be explained by stronger surface interactions due to the smaller particulate size with higher specific surface area.

CONCLUSIONS: The decrease in particle size and increase in specific surface area showed an enhancement in bone augmentation by fostering particle-gel-bone interactions. These results make this material combination a promising one as it also carries the potential to minimize interference with the bone healing cascade compared to self-setting materials.

INTRODUCTION: Poly(2-oxazolines) (Pox) are amphiphilic, non-ionic polymers used in medical and drug delivery applications. They can be conjugated with drugs, peptides and proteins. In this study we intend to use model Pox to modify surface of poly(L-lactide-co-glycolide) (PLGA) membranes. The membranes were produced by one-step phase separation process between poly(ethylene glycol) (PEG), PLGA and Pox, dissolved in dichloromethane (DCM) followed by PEG leaching.

METHODS: PLGA (85:15, Mn=100kDa, d=1.9), PEG (400 Da) and POx (methyl-P[MeOx37-b-BuOx-23-b-MeOx37-pipeidine(P2-P2) (Mn=8 kDa, d=1.14) were dissolved in DCM, casted on Petri dishes, dried and immersed in UHQ-water for PEG leaching to obtain membranes (M_Pox). As a reference PLGA membranes (M) and PLGA foils without Pox (Foil) were made. Micro-structure of the samples was observed under scanning electron microscopy (SEM). Water contact angle and FTIR spectroscopy was used to characterise the materials. Cytocompatibility tests were performed with osteoblast-like MG-63 cells for 24 h, 3 and 7 days. Viability was measured by resazurin reduction; phalloidin/DAPI and live/dead staining tests were done.

RESULTS & DISCUSSION: Phase separation between PLGA and PEG followed by PEG leaching was found useful in producing porous membranes. Addition of Pox influenced topography of the M-Pox, by decreasing average pore size on the upper side of the membrane and decreasing water contact angle (data not shown). Cells cultured on all membranes were better spread and had better developed actin fibres as compared to cells cultured on foils for 24 h. Cell viability on days 3 and 7 was also significantly higher on the membranes than on the foils.

CONCLUSIONS: One-step phase separation process between PLGA, PEG and Pox, dissolved in DCM followed by PEG leaching resulted in membranes, which were found cytocompatible with osteoblast-like cells.

INTRODUCTION: When bone fracture occurs, body can repair itself. But, if the size of the defect is superior to a critical size, bone substitutes can be used [1]. The aim of bone substitute is to repair bone defect. Chemical treatments are applied on bone substitutes to ensure a high level of safety. But these treatments can affect the quality and quantity of proteins contained in bone substitute. The aim of Proteobios Lab is to analyse as much as possible proteins present in bone substitutes of natural origin and evaluate their effect on stem cells.

METHODS: Bone substitute is finely ground to produce a homogeneous powder using grinder. Bone substitute powder is decalcified with acidic solution overnight, incubated with extraction buffer and proteins are digested with trypsin. Then peptides are identified using mass spectrometers. Identified proteins are classified according biological processes and molecular functions, and proteins interactions analyzed using STRING online proteins database.

RESULTS & DISCUSSION: More than 80 proteins were identified byNanoLC/MS-MS. With STRING online proteins database, interactions between proteins can be studied.

CONCLUSIONS: Proteomic is a smart and efficient tool to analyze the composition of bone substitute. Protein composition, biological process, molecular function and interactions between proteins were analyzed.

Figure 1: Identified proteins of natural biomaterial are involved in biological processes such as ossification, bone morphogenesis, regulation of bone mineralization and are also implicated in molecular functions such as calcium binding and glycosaminoglycan binding. The network view summarizes the network of predicted associations of groups of proteins. Nodes represent proteins and edges represent the predicted functional associations.

Recent advances on application of small molecules as osteogenic inducers
A. Ahmadi, S.S. Ebadi, R. Mazloomnejad-Meybodi, N. Halvaei, H. Niknejad
Presenting Author: Armin Ahmadi, arminahmadi@sbmu.ac.ir

INTRODUCTION: high morbidity rates alongside with significant costs for the healthcare system are some of the cons of current treatment methods of bone defects [1]. Stem cell-based methods are considered to be a possible substitute. Since the discovery of stem cells, guiding them towards osteogenic lineages has been an area of great attention. Agents administered to differentiate stem cells have generally been natural growth factors including BMPs and IGFs combined with genetic engineering methods and small molecules. Due to expensiveness and difficulty of access, growth factors do not provide a widely practical clinical application. Small molecules are subjects of a growing body of experiments because of not having the mentioned problems. Therefore, we suggested here that knowledge of small molecule mediated osteogenic differentiation is necessary in order to investigate clinical applications of tissue engineering methods regarding treatment of bone defects.

METHODS: Keywords searched included “stem cell differentiation”, “small molecules”, “osteogenic differentiation” and “in vitro”, “in vivo” and “clinical application”. The main databases used were “google scholar” and “Pubmed”. More than 200 papers were found, from which 120 were selected based on their relevance, year of publishment and number of citations.

RESULTS & DISCUSSION: Many molecules, including Statins, metformin and Phenamil widely known to operate through specific cellular pathways have also been found to affect other pathways within the cells resulting in complex intracellular signalings leading to osteogenic differentiation. Bisphosphonates and Dexamethasone are also known to induce osteogenesis. The importance of these molecules as well as non-pharmacologic molecules synthesized solely for the purpose of experimentation, like T63, SAG and THQ-1a are of no question. Simvastatin, Phenamil, Adenosine, T63, Alendronate and Stronium ranelate are among the agents that have promoted osteogenic differentiation in vivo. Recently, Simvastatin, in a clinical study has been shown to induce osteogenesis in surgically removed third molars in a faster motion. Further investigations are needed to elucidate whether or not these molecules can replace natural growth factors totally in this matter.

CONCLUSIONS: All in all, this study states that small molecule-based osteogenic differentiation is proposed as a promising treatment method of bone defects including nonunion fractures and osteoporosis in the future.

Electrospun nanofiber yarns as sutures to repair wounds
A. Richard¹, R. S. Verma¹
Presenting Author: Arthi Richard, arthihard@gmail.com
¹Department of Biotechnology, Indian Institute of Technology, Madras, India

INTRODUCTION: Sutures are the most common medical devices used for surgical procedures [1]. The twisted strand of Electrospun polymer nanofiber yarn has gained attention due to the advantages of high surface area, increased mechanical strength and drug release properties for improved suture material [2,3].

METHODS: Electrospun Polylactic acid nanofibers were modified to form yarns using a funnel collector rotating at high speed placed perpendicular to the needle connected to high voltage supply. The polymer nanofiber yarns were initiated by drawing using a grounded metal rod and wound to bobbin. The formation of continuous yarns was optimised at rotating speed of 400,500 and 600 rpm. Mechanical testing was performed according to ASTM D226

RESULTS & DISCUSSION: Physical characterisation of Polymer nanofiber yarns spun at different rotating speed were analysed by Scanning Electron Microscopy. the diameter of the yarn was in the range of 170-190μm. The increase in speed leads to decrease in diameter of the yarn and increase in twist. Mechanical characterisation of the yarn at different rotating speed were tested by ASTM D226 with Tensile stress in the range of 0.05MPa.

CONCLUSIONS: SEM data and tensile testing data clearly illustrate the high surface area of nanofibers twisted together as nanoyarns and appropriate mechanical strength provides cues for use of nanofiber yarns as a building block to fabricate suture in twisted or braided form to repair wounds.

INTRODUCTION: Chitosan (CS)/Gelatin (G)/nanohydroxyapatite (nHAp) blends have been applied as promising scaffold materials for mineralized tissue - primarily bone - regeneration [1, 2]. However, little is known whether they could be used as suitable scaffolds to stimulate the differentiation of dental pulp stem cells (DPSCs) into odontoblastic lineages to induce dentin regeneration. Aim of this study was to develop biomimetic CS/G/nHAp scaffolds to be used as carriers of DPSCs for targeted dentin regeneration.

METHODS: Scaffolds were prepared by keeping the ratio 3:1:1 of the three solid components, i.e. nHAp, CS, and G and dissolving into a 3 w/v % thoroughly stirred nHAp powder in deionized water dispersion, a 2 w/v % CS in 1 v/v % acetic acid solution and a 2 w/v% G in ultrapure water solution and stirring for 2 h at 50 °C. The mixture was casted in 24 well plates, lyophilized for 24 h, crosslinked with 0.1 % glutaraldehyde and lyophilized again. The scaffolds were characterized by means of SEM, EDS, TGA, FTIR and XRD. DPSC cultures were established from healthy donors and characterized for stem cell markers with flow cytometry. Scaffolds were seeded with DPSCs in complete culture medium (CCM: α-MEM with 15% FBS, 100 mM L-ascorbic and antibiotics/antimycotics). SEM was used to evaluate cell attachment/morphology within the scaffolds. Live/dead staining visualized by confocal microscopy was used to evaluate cell viability, and real time PCR for the expression of odontogenic genes.

RESULTS & DISCUSSION: Scaffolds with interconnective pores with an average size 100 μm were prepared and physicochemically characterized. SEM analysis up to day 14 revealed that CS/G/nHAp scaffolds favour the attachment of DPSCs. Live/dead staining confirmed that most cells (>90%) remained viable throughout the entire culture period in both types of scaffolds. Significant and time-dependent (p<0.05) upregulation of odontogenic differentiation genes, including alkaline phosphatase, bone morphogenetic protein 2, dentin sialophosphoprotein, and osteocalcin was observed in DPSC-seeded scaffolds over a period of 14 days.

CONCLUSIONS: CS/G/nHAp hybrid scaffolds supported attachment, viability and odontogenic differentiation of DPSCs in vitro revealing a promising strategy for their application in targeted dentin regeneration.

INTRODUCTION: Tissue engineering (TE) may provide effective alternative treatment for challenging temporomandibular joint (TMJ) pathologies associated with disc malpositioning or degeneration leading to severe masticatory dysfunction. Aim of this study was to evaluate the potential of chitosan/gelatin (Ch/Gel) scaffolds seeded with dental pulp stem cells (DPSCs) and cultured in a perfusion bioreactor to promote fibro/chondrogenic differentiation and production of fibrocartilage tissue, serving as a replacement of the natural TMJ disc.

METHODS: Porous Ch/Gel scaffolds, with a composition of 40%-60% chitosan-gelatin, were fabricated by chemical crosslinking with 0.1% glutaraldehyde and lyophilization. DPSCs were isolated from third molars and seeded onto the Ch/Gel scaffolds (2x10⁶ cells/scaffold). DPSC/scaffold constructs were cultured under normoxic (20% O₂) or hypoxic (5% O₂) conditions. For the viability assay constructs were cultured with standard culture medium, while for the assessment of differentiation constructs were cultured with chondrogenic medium. Live/dead staining was used to evaluate cell attachment and viability after 3, 7 and 14 days in culture. Real time PCR was used to evaluate the expression of specific fibro/chondrogenic markers (Collagen I-COLI, Collagen X-COLX, Sox9-SOX9) after 7 and 14 days in culture. After 4 weeks in static culture, one group of DPSC/scaffold constructs was placed in the perfusion bioreactor (10 ml/min) and further cultured for 4 weeks. DPSC/scaffold constructs were assessed for extracellular matrix production by means of histology and dynamic mechanical analysis after 4 and 8 weeks.

RESULTS & DISCUSSION: Live/dead staining showed that more than 90% of the cells remained viable inside the scaffolds in both conditions. DPSCs cultured into Ch/Gel scaffolds under hypoxic conditions demonstrated a significant increase of gene expression of fibrocartilaginous markers (COLI, COLX, SOX9) after 2 weeks in culture compared to normoxic conditions. Histological data after 8 weeks indicated that only the constructs cultured in the perfusion bioreactor support abundant fibrocartilaginous tissue formation. Dynamic mechanical analysis revealed increased yield strain of the constructs cultured under dynamic conditions compared to static ones.

CONCLUSIONS: Collectively, these data provide evidence of a promising strategy for TMJ disc TE-based replacement, by application of natural biomaterials combined with dental-tissue derived mesenchymal stem cells.

INTRODUCTION: During wound healing process, proliferation of stromal cells is one of the important stages for granulation, contraction and re-epithelialization. Proliferation occurs in three-dimensional (3D) environment in vivo and granulation involves cell crawling of fibroblasts to fill the wound bed. The purpose of this study is to understand the working mechanism of fibroblasts migration via our 3D wound model and to investigate the way how cells migrate and close the gap on varying geometries of 3D microgap.

METHODS: 3D microgap with varying gaps from 100-300 μm was fabricated by pouring polydimethylsiloxane (PDMS) on patterned mold. After solidification process, PDMS was peeled off and then coated with polydopamine (PDA). NIH 3T3 cells were used in this work. Both 25 μM of blebbistatin and Y-27632 were added to the cell culture media for inhibition of contractility of myosin II and Rho-associated protein kinase (ROCK), respectively. Live cell microscopy was used to monitor the migration of cells closing the gaps while confocal microscopy was employed for immunofluorescence images.

RESULTS & DISCUSSION: Phase contrast live cell and confocal microscopies reveal that cells close the gap on 3D microgap through contractility of myosin II including ROCK and adherens junction (Figure 1). These lead to supracellular actomyosin contractility, a mechanism that was mostly found on 2D planar substrate using epithelial cells [1]. Decay of area over time shows that even at larger gaps the closure of gaps is linear (Figure 1).

CONCLUSIONS: Our study show a complete dependence of 3D microgap closure on both cellular contractility of myosin II and ROCK.

Figure 1: Phase contrast images show that NIH 3T3 cells close a microgap with time. Yellow line is the boundary of the 3D microgap. Scale bars are 100 μm. a. Immunofluorescence of F-actin and nucleus on 3D microgap during gap closure. Scale bar is 100 μm. b. Decay of area over time with different gap diameters (100-300 μm). c and d. Gap closure is mediated by contractility of myosin II and ROCK.

INTRODUCTION: Despite numerous extrusion-based approaches developed in the field of 3D bioprinting, there is still a lack of understanding of the general process of this technology. To better understand the nature of extrusion-based bioprinting, we aimed to investigate the general criteria through progressively developing feasible bioprinting processes for different bioinks.

MATERIALS & METHODS: All the case studies followed the similar route as showed in Fig 1 (left), where bioink was extruded to form gel filaments for 3D construct fabrication. Bioinks with various gelation properties were studied, including guest-host self-assembly, thermal gelation and photo-crosslinking. The bioprinting process was optimized corresponding to specific bioink based on either home-made or commercial (e.g., SunP Biotech) bioprinters. For examples, temperature and light were well controlled for printing thermo-responsive and photo-crosslinkable hydrogels, respectively. General characterizations of the bioprinting outcome include 3D printability, construct stability, cell viability, and functionality.

RESULTS & DISCUSSION: Three cases were studied independently, starting with gel filament generation and ending with cell viability maintenance. The shear-thinning and self-healing formulation (guest-host hyaluronic acid) was demonstrated to support consistent extrusion and maintenance of hydrogel shape, and additional secondary crosslinking helped to further stabilize the structure (Fig 1, right A). With careful control of temperature in the nozzle and printing platform, gelatin-based bioink could be successfully printed, maintaining good 3D printability and cell viability (> 90%) (Fig 1 right B). By simultaneously introducing light to a light-permeable nozzle during printing, various non-viscous photo-crosslinkable bioinks could be printed into 3D constructs (Fig 1 right C).

CONCLUSIONS: General requirements for bioink and bioprinting process include biocompatibility, consistent injectability, filament maintenance, co-adhesion between layers, further stability and low shear force on cells.

Figure 1: (left) Schematic of extrusion-based bioprinting process, showing general criteria in each step. (right) Bio-3DP examples based on (A) shear-thinning and self-assembly, (B) thermo-responsive, and (C) photo-crosslinkable hydrogel formulations.

INTRODUCTION: There is a number of patients suffering from problems caused by torn ligaments or tendons. In 20% of cases, treatment with traditional methods, does not produce lasting results. It has very negative consequences for patients’ life. We have used sonocoating method to deposit hydroxyapatite nanoparticles on ligament’s fibers. It will cause bone ingrowth between the fibers of ligament, firmly attaching to the bone tissue and strengthening the connection between ligament and bone tissue. We are developing sonocoating technology to be brought into the clinical phase level of the study.

METHODS: We were investigating the influence of coating conditions (coating duration, suspension concentration) in order to obtain homogeneous layer on the fiber’s surface. Four types of nanohydroxyapatite particles (nHAP) were selected. Textile fabric was fixed on holder and immersed in ultrasonic chamber with nHAP suspension. Subsequently, ultrasonic waves were induced nearby material in order to deposit nHAP on its surface. Research are based on SEM investigations and weight change analysis.

RESULTS & DISCUSSION: Homogeneous layers of nHAP were produced using sonocoating method. It was proved that nHAP layer structure depends on nanoparticles size, coating duration and suspension concentration. Lengthening coating time and increasing suspensions concentration results in higher amount of hydroxyapatite deposited on the surface. Sonocoating method have beneficial conditions as it occurs in water, room temperature and short coating duration.

CONCLUSIONS: The novel method of nHA deposition on the polymeric fibers can serve as an alternative for currently known orthopaedic implants modification solutions. Material testing revealed good stability and bioactivity of the deposited nHA coating in SBF. The immersion test of the in vivo bone bioactivity prediction in SBF can reduce the number of animals used in and the duration of future animal experiments.

Methylcellulose as a smart thermosensitive scaffold material for tissue engineering
B. Niemczyk, P. Sajkiewicz, A. Gradys
Presenting Author: Beata Niemczyk, bniemczyk21@gmail.com
Laboratory of Polymers and Biomaterials, Institute of Fundamental Technological Research, Polish Academy of Sciences, Warsaw, Poland

INTRODUCTION: Injectable thermosensitive hydrogels can be rapidly introduced into the body by injection, thus help to avoid complex and long surgeries. Methylcellulose (MC) aqueous solution, while heated up to near 37°C, as an effect of dehydration, undergoes physical two-step crosslinking [1]. Injectable ability of such hydrogel system at room temperature and crosslinking during subsequent heating to physiological temperature make such approach attractive for tissue engineering. The objective of this study was to investigate the crosslinking kinetics, biological properties and injection ability of MC aqueous solution, what was studied at various concentrations.

METHODS: Methylcellulose METHOCEL A15LV (Sigma Aldrich) was prepared at various (w/w %) concentrations in demineralized water. The cross-linking kinetics was studied by differential scanning calorimetry (DSC) at the heating rate of 2 K/min, in the temperature range 20-80°C. In order to prevent water evaporation, hermetic pans were used. Biological tests of hydrogels were performed using L929 fibroblasts. MTT cytotoxicity test was carried out on extracts. Injectability tests allowed determination of the maximum force (should be lower than 30 N [2]), which is needed to carry out injection of the hydrogel into medium that simulates native tissue at 37°C.

RESULTS & DISCUSSION: DSC results show complex thermal behavior with upmost two small endothermic effects, shifting to lower temperatures with increase in MC concentration. For MC concentration higher than 6%, low temperature peak disappears, leaving only the high temperature peak. Analysis of the kinetics of the effects indicates that the rates of the two cross-linking processes increase with temperature and decrease with MC concentration. MTT cytotoxicity tests showed that this type of materials are not cytotoxic. For all MC concentrations the injectability tests showed the maximum force below 30 N.

CONCLUSIONS: Depending on MC concentration, the MC cross-linking may be two- or one-step process. Two-step cross-linking process, which takes place at lower MC concentrations, seems to proceed at higher rates, which is probably due to higher chain mobility of diluted solutions and due to higher temperature. Injectability tests prove that all of the investigated hydrogel concentrations can be easily injected.

An insight into the bioadhesives of the ixodid ticks Amblyomma hebraeum and Dermacentor marginatus
B. Engel¹, J. Suppan², S. Nürnberger², M. Marchetti-Deschmann¹
Presenting Author: Benedikt Engel, benedikt.engel@tuwien.ac.at
¹Institute of Chemical Technologies and Analytics, TU Wien, Vienna, Austria ²Department of Orthopedics and Trauma Surgery, Medical University of Vienna, Austria

INTRODUCTION: Ticks’ salivary glands produce a sticky secretion called attachment cement. This biological adhesive is a mainly proteinaceous substance and hardens rapidly when secreted. However, the functions of the cement are not fully understood yet, but it is suggested that besides other functions it mainly strengthens the attachment of the ticks’ mouthparts to the vertebrate host during their blood meal [1]. In this work we present bioanalytical results for tick cement to get a deeper insight into its biochemical composition.

METHODS: Tick cement was collected from in vitro fed Amblyomma hebraeum and Dermacentor marginatus, both ixodid ticks. After homo-genization by grinding, portions of the cement were used for amino acid analysis by GC-EI-MS/MS (gas chromatography electron ionization tandem mass spectrometry). SDS-PAGE (sodium dodecyl sulphate polyacrylamide gel electrophoresis) was carried out to separate proteins and subsequently identify them from respective gel bands. Proteolytic peptides resulting from in-gel digestion were analysed by LC-ESI -MS/MS (liquid chromatography electrospray ionization tandem mass spectrometry). Data evaluation of the obtained MS and MS/MS spectra was carried out with PLGS (ProteinLynx Global Server, Waters) in order to identify tick cement proteins.

RESULTS & DISCUSSION: Amino acid analysis after acid hydrolysis revealed that the cement mainly consists of non-polar amino acids and glycine as the major component. Our findings are in good agreement with amino acid compositions theoretically calculated from genomic data [2]. Different buffer systems allowed solubilisation of proteins, however some insoluble debris was always observed. Proteins between 20 and 80 kDa were separated by SDS-PAGE. The identification of bovine proteins confirms that the feeding material, containing bovine blood, contaminates the cement. Therefore tick specific protein identification was challenging. In addition to that the lack of reviewed database entries impedes protein identification. Nevertheless we were able to identify cement specific proteins (e.g. cement protein RIM36). The identification of proteins named glycine rich proteins confirms the high amount of glycine found by amino acid analysis.

CONCLUSIONS: The ability of ticks to adhere to their host skin makes the secreted cement a very interesting field of research as such an adhesive could be used in medicine for various applications. This work allowed to get an insight into the amino acid and protein composition of the cement of two tick species which in future might help to understand the attachment mechanism.

INTRODUCTION: Nucleus Pulposus Progenitor Cells (NPPCs), positive for the angiopoietin-1 receptor (Tie2), were demonstrated in human, mouse, canine and bovine NP tissue [1,2,3]. Tie2+ NPPCs possess a multi-lineage differentiation potential, and regeneration potential is attributed to them. However, the isolation of Tie2+ NPPCs can be cumbersome. Hence, three isolation methods were compared.

METHODS: Bovine NP cells were isolated from 10-14-month-old animals. Cell sorting was performed with an antibody against Tie2 (bs-1300R, Bioss) using FACS, magnetic-activated cell sorting (MACS) and pluriSelect, a size-based sorting method. Outcomes were evaluated by cell yield of Tie2+ cells, the ability of sorted cells to form colonies and tri-lineage differentiation assays.

RESULTS & DISCUSSION: FACS resulted in the highest Tie2+ cell yield (5.0 ± 4.0%) followed by MACS (1.6 ± 2.9%) and pluriSelect (1.1 ± 1.4%). Colony forming ability did not differ between Tie2+ and Tie2- cells for any isolation method. However, Tie2+ cells obtained by MACS tended to have more colonies than FACS and pluriSelect. Osteogenic and adipogenic differentiation of Tie2+ and Tie2- cells did not result in a clear distinction for MACS and pluriSelect; Tie2+ FACS-sorted cells demonstrated superior osteogenic and adipogenic differentiation over Tie2- cells. Also for chondrogenesis, the Tie2+ FACS-sorted Tie2+ NPPCs tended to produce more proteoglycan versus Tie2- NPPCs, whereas for MACS and pluriSelect no difference was found.

CONCLUSIONS: Based on the parameters tested, isolation of NPPC is possible with all three methods. However, cell yields differed widely. FACS although most invasive, appears to be the most specific sorting method for these Tie2+ cells among the tested methods as Tie2+ cells do not demonstrate osteogenic and adipogenic differentiation. As for cell yield MACS seems to reveal the most, possibly this is due to inclusion of cells expressing Tie2 less strongly.

INTRODUCTION: Mesenchymal stromal cells (MSC) have been identified as important cell-based therapy candidates for cartilage, bone and intervertebral disc diseases [1]. During prolonged in vitro expansion prior to administration, MSC become senescent which impairs their therapeutic potential [2]. Here, we aimed to investigate whether extracellular nicotinamide riboside (NR) is beneficial for MSC expansion with respect to delaying the senescence, improving cellular activity and growth kinetics.

METHODS: MSC were isolated from human bone marrow aspirates by gradient centrifugation of the bone marrow and subsequent expansion in α-MEM + 10% fetal bovine serum + 2.5 ng/ml bFGF-2. The cytotoxicity of NR was measured at day 4 for 29 concentrations in a range from 5 nM to 4 mM. The long-term effects of NR were tested at concentrations of 10, 100 and 1,000 μM by measuring the population doubling level (PDL), relative confluency (real-time live-cell imaging with IncuCyte S3®), mitochondrial activity by resazurin reduction, senescence-associated β-galactosidase assay (SA-β-gal) and NAD/NADH ratio.

RESULTS & DISCUSSION: MSC treated with 3 and 4 mM NR had a significantly higher mitochondrial activity at day 4 than the negative control (p=0.0027 and p<0.0001 respectively, N=3). However, in the weeks 3 to 8, cells treated with ≥100 μM NR died reaching a maximum PDL of 13.43 (N=4). In two donors, the experimental group with 10 μM NR reached a 2-fold higher PDL than the negative control. The relative confluency at passage (P) 2 after 6 days in culture was higher with 10 μM NR compared to the negative control (35.00 ± 9.29% and 26.19 ± 5.41% respectively, mean ± SD, N=2). The mitochondrial activity was significantly higher with 10 μM NR at P4, P8 and P10 (p<0.01, N=4). At all passages, the percentage of SA-β-gal positive cells was under 5%, except in the negative control medium at P11 (18.17% ± 18.18%, mean ± SD, N=1). All experimental groups treated with NR had a higher NAD/NADH ratio which exhibited a dose-dependent trend (N=1).

CONCLUSIONS: Extracellular NR elevated the intracellular NAD/NADH ratio. NR is not cytotoxic within 4 days of culture at concentrations up to 4 mM. Long-term culture with 10 μM NR improved the growth kinetics markedly in two donors.

INTRODUCTION: Emulsion templating is an emergent manufacturing route for producing highly porous scaffolds (PolyHIPEs) with interconnected porosity. In this paper, we present the development of PolyHIPEs made of photocurable 4-arm polycaprolactone methacrylate (4PCLMA) which is one of the most extensively used synthetic, biocompatible and bioresorbable polymers, used as a scaffold material for both hard and soft tissues. The viscosity of the PCL pre-polymer is high which can lead to destabilisation of the emulsion. Here solvent dilution was used to reduce the viscosity of PCL to enable creation of an emulsion. The effect of solvent composition and volume on emulsion stability and morphology was investigated and the interplay between solvent and oil phase densities was analysed.

METHODS: By using various solvents/solvent blends PolyHIPE compositions were created and their morphologies, stabilities and mechanical properties were tested. Human dermal fibroblasts were cultured on both the produced PolyHIPEs and a control scaffold (commercial polyHIPE scaffold, Alvets®). Cytotoxicity was evaluated comparing cell viability. Cell attachment and infiltration were investigated via SEM and histological staining, respectively.

RESULTS & DISCUSSION: Stable PolyHIPE foams consist of fully PCL was developed successfully. Chloroform was found to be a better porogenic solvent to dilute the PCL and creating porous scaffolds. Alternatively, when toluene was used to dilute the oil phase, HIPEs were found to be more stable. Both open porous and comparably stable HIPEs were successfully created when solvent blends of both chloroform and toluene were used to dilute the oil phase. Pore and window size of the 4PCLMA PolyHIPEs were shown to be tunable by adjusting the chloroform and toluene ratios in the solvent blend. These changes in morphology have an effect on mechanical properties. 4PCLMA PolyHIPE scaffolds were shown to be capable of supporting cell attachment, growth, and migration within the scaffold.

CONCLUSIONS: Understanding effect of solvent volume and composition on morphology and the mechanical properties of the scaffold, enable us to control scaffold properties. By controlling the conditions, a scaffolds architecture and mechanical characteristic can be tailored for various tissue engineering applications.

INTRODUCTION: In the fast growing field of regenerative medicine, it is more important than ever to analyze tissue structures or implant-interface interaction. Beyond, easy and gentle preparation of scaffolds or biomaterials for use in tissue engineering is desirable. Current technologies for cutting hard tissue, scaffolds or biomaterials lack of preciseness, 3D function or the ability to process the material at a sufficient quality. Femtosecond laser based cutting combined with Optical Coherence Tomography (OCT) imaging offers new roads for material processing as demonstrated at different applications out of a broad range of applications in regenerative medicine.

METHODS: a) For histology sections from orthopedic or cardiovascular resin embedded samples were cut using a laser microtome, hard tissue without prior decalcification. Stainings were applied as indicated in the results. b) For site-specific 3D-sectioning of native tissue, regions of interest at bone-titanium interfaces of a fresh rat tibia were determined by OCT. Then small volumes were cut (~300x300x300 µm). Harvested tissue was further processed for TNF-alpha gene expression analysis. c) Laser preparation of native or fixed pericardium, hard valves tissue layers or cornea was performed as indicated in the results.

RESULTS & DISCUSSION: a) A broad range of histological stainings and even immunohistochemistry can be successfully applied to thin sections performed by laser microtomy. The sections show tissue architecture and cellular details clearly. b) Image-guided collection of native tissue samples along an implant could be demonstrated successfully (Fig.1). A fresh rat tibia with a dental implant was imaged by OCT to identify new formed bone along the implant. This bone and control samples from surrounding areas were cut out and subsequently analyzed for TNF-alpha expression. Enhanced site specific expression at the interface was observed. c) Separation of heart valve elastin from collagen layer was successfully performed, as also separation of cornea epithelium. Laser sectioning of pericardium for further tissue engineering purposes resulted in precise cutting without any visible detriments.

CONCLUSIONS: Collectively, these data clearly illustrate that image guided femtosecond laser based tissue and material sectioning opens new dimensions for tissue processing, histological and biochemical tissue analysis in regenerative medicine.

Figure 1: Gentle laser based isolation of new formed bone along a dental implant in a rat tibia. a) OCT of rat tibia with dental implant (*). New formed bone along implant (>). b) Areas of interest was cut out successfully (arrow).

INTRODUCTION: Phytochemicals present in the areca nut extract (ANE) such as arecoline along with high Cu$^{2+}$ has a strong fibrotic effect on tissues. Chewing of areca nuts is a habit among people in the Indian subcontinent triggering precancer condition such as the oral submucous fibrosis. Post-operative/post-biopsy healing on a stiff fibrotic tissue ambiance is thus important. Here we document the behavior of post-injury fibrotic scarring on a stiffened skin with arecanut induced fibrosis.

METHODS: Arecoline was extracted by methanol based solvent extraction from arecanut. The powder was obtained by sequential removal of solvents by rotary-evaporation and freeze drying. The extract was applied on mouse skin dorsum (35-40 gm, all males, 6 months age, Mus musculus) to cause fibrosis and a wound was made at the fibrotic site. Optical Coherence Tomography (OCT, Thorlabs, USA) was used to image the wound healing cross-sections in vivo. Animal studies were performed as per the Institute Animal Ethical Committee guidelines.

RESULTS & DISCUSSION: The extract showed a high content of arecoline (Fig 1a). On treatment with ANE, within 30 days, the dermis showed contraction and hypodermis started to disappear (Fig 1 b, c). Upon withdrawal of the ANE, the hypodermis layer started to appear (Fig 1 d). The scar in the normal skin contracted more than the surrounding giving a hammock-like appearance (Fig 1 e). Scars in fibrotic skin, the optical intensities closely matched the fibrotic ambiance (Fig 1 f, g) without a hammock-like appearance of the scar. We found that the optical scattering intensity ratio between the scar and the ambiance was highest in normal skin, followed by the fibrotic bed with continued and withdrawn treatments of ANE (Fig 1 h).

CONCLUSIONS: We found that upon healing, the scar tissue blends better with the fibrotic tissue ambiance after the ANE treatment was withdrawn.

ACKNOWLEDGEMENTS: Funded by Dept. of Biotechnology, Govt. of India.

INTRODUCTION: The combination of four different microRNAs (miR-1, 133, 208 and 499), named “miRcombo”, has been used for the direct reprogramming of murine fibroblasts into cardiomyocytes (CMs) for myocardial infarction (MI) treatments.[1,2] Here, we evaluated miRcombo mediated reprogramming of human adult cardiac fibroblasts (AHCFs) into CMs in 2D and 3D culture.

METHODS: For digital droplet PCR (ddPCR) analysis, 3x10^5 AHCFs were plated in 6-well plates, for Immunocytochemistry (ICC) 5x10^4 cells were plated in 24-well plates. AHCFs were transfected with miRcombo (mirVana) using DharmaFECT1 (Dharmacon). Untrasfected and NegmiR (mirVana) transfected AHCFs were used as controls. After 24 hours, medium was changed to medium with 1 μM Jak1 Inhibitor for 4 days for 2D experiments; for 3D experiments, cells were cultured in fibrin-based hydrogels.

RESULTS & DISCUSSION: ddPCR analysis showed significant increase expression of early cardiac transcription factors (TFs) Hand2 and MeF2c (p < 0.005) slight increase expression of Tbx5 and Nkx2.5, although non-significant (p > 0.05), and reduced Vimentin expression (p < 0.05) in miRcombo-transfected AHCFs compared to controls after 4 days in 2D culture. ICC analysis showed increased expression of late cardiac markers α-sarcomeric actinin and cTnT in miRcombo-transfected AHCFs after 10 and 20 days of culture in 2D. However, ddPCR showed no significant differences of late cardiac markers Myh6 and cTnI expression between the groups after 15 days in 2D culture. On the other hand, cells cultured in 3D fibrin-based hydrogels showed enhanced cardiac TFs expression compared to 2D. However, miRcombo transfection did not significantly enhance cardiac gene expression in AHCFs cultured in 3D hydrogels respect to controls after 4 days. After 15 days, AHCFs cultured in 3D hydrogels showed a strongly enhanced expression of cardiac genes such as cTnI and Myh6 compared to 2D.

CONCLUSIONS: Together, these results showed that a 3D environment was found to play a key role in enhancing direct reprogramming of AHCFs into CMs.

Gene repression of the CREB transcription factor promotes the healing of wounded human tissue-engineered corneas

INTRODUCTION: The cornea composes the outer surface of the eye and its transparency is required to allow light transmission to the retina. However, because of its position, the cornea is subjected to chemical and mechanical injuries that may lead to blindness. In our laboratory, we demonstrated that activation of the transcription factor cAMP-response element binding protein (CREB) is reduced during corneal wound healing in human tissue-engineered corneas (hTECs) and that addition of the CREB inhibitor C646 considerably accelerates wound closure [1]. To alter CREB gene expression in a more specific manner, the dCas9-KRAB system was used to suppress or reduce its expression in human corneal epithelial cells (hCECs).

METHODS: Four different single guide (sg) RNAs complementary to four distinct regions from the CREB gene bearing DNA target sites for transcription factors reported to contribute to CREB gene expression were designed and cloned into the pLV hU6-sgRNA hUbC-dCas9-KRAB-T2a-GFP plasmid [2]. These plasmids, each containing one of the four sgRNAs, were transfected by electroporation into HCECs. The capacity of each sgRNA to reduce or suppress the expression of the CREB protein when transfected into hCECs was then evaluated by Western Blot and Electrophoretic Mobility Shift Assay (EMSA). HCECs in which expression of CREB has been reduced to various levels were then used for the production of hTECs that were used in wound healing assays.

RESULTS & DISCUSSION: Transfection of the sg1 RNA allowed for the complete suppression of total CREB expression whereas the sg2, sg3 and sg4 RNAs reduced its expression to varying levels (42.20%, 93.83% and 94.81%, respectively). Phosphorylated CREB expression was also considerably reduced (between 90% and 100% for each sgRNA). These results were further supported by the demonstration that each sgRNA considerably impaired the binding of CREB to its DNA target site in EMSA. The production of hTECs with CREB-deficient hCECs and their use in wound healing studies is actually underway.

CONCLUSIONS: The dCas9-KRAB system is particularly effective at reducing the expression of CREB in hCECs. We believe that the functional characterisation of CREB in corneal wound healing will help develop therapeutic strategies aimed at improving corneal wound healing in patients.

INTRODUCTION: Cardiovascular diseases are the primary cause of death globally, responsible for approximately 17.5 million deaths per year. In particular, myocardial infarction caused by the obstruction of a coronary artery can lead to heart failure. A growing number of studies have demonstrated that extracellular vesicles (EVs) exhibit great potential as cell-free cardioprotective agents, which could overcome many of the technical, ethical and regulatory hurdles associated with cell-based therapies [1-3]. However, the beneficial effects of administered EVs are short-lived; a major limitation that could be circumvented using a material-based approach for increased retention and sustained release. Therefore, the main objective of this study was to develop a feasible approach for repairing the infarcted heart, in the form of injectable, ‘off-the-shelf’ EV-loaded synthetic microgels. This platform was designed to improve EV stability and retention time at the site of administration, with sustained and environmentally-responsive release of EVs to the surrounding damaged tissue.

METHODS: We developed a droplet-based microfluidic platform enabling high-throughput fabrication of monodisperse, injectable EV-loaded microgels composed of multi-arm poly(ethylene glycol) (PEG) crosslinked with enzyme degradeable peptides.

RESULTS & DISCUSSION: This hydrogel composition enabled controlled microgel degradation and EV release over a period of at least four days in the presence of specific matrix metalloproteinases that are upregulated in heart tissue after myocardial infarction. This delivery system was validated by monitoring the release of EVs containing a Bioluminescence Resonance Energy Transfer construct. This method enabled EV quantification and validation of sustained bioactivity both in vitro and in vivo.

CONCLUSIONS: Taken together, these results demonstrate that EVs can be successfully encapsulated and controllably released via an injectable and biodegradable microgel system. Future work will focus on verifying EV stability in the microgels over time, and ultimately delivering therapeutic EVs in vivo for repair of the infarcted heart.

INTRODUCTION: Stroke is a major health problem with limited treatment options. According to the World Health Organisation, stroke is the second leading cause of death worldwide accounting for 6.7 million deaths annually and for surviving patients, nearly two thirds will be left with some disability. In recent years, interest in the development of biomaterial-based therapies to promote brain repair and functional recovery has increased exponentially. A broad range of strategies have been investigated including nanoparticles or liposomes as delivery vehicles for drugs and scaffolds as structural support for tissue regeneration. Despite interest in this area, no systematic review and meta-analysis has so far been conducted assessing the efficacy of these biomaterial-based approaches.

METHODS: Studies were identified by searching electronic databases and reference lists of relevant review articles. Studies reporting lesion volume (brain damage) and/or neurological score as outcome measures were included. Standardised mean difference (SMD) and 95% confidence intervals were calculated using DerSimonian and Laird random effects. The CAMARADES (Collaborative Approach to Meta-analysis and Review of Animal Data in Experimental Studies) checklist was used to assess study quality. Publication bias was then visualised by funnel plots followed by trim and fill analysis of missing publications.

RESULTS & DISCUSSION: Sixty six publications were included in the systematic review, of which 48 (88 comparisons) were assessed in the meta-analysis. Overall, biomaterial-based interventions reduced stroke damage (SMD: -1.56, 95% CI: -2.0, -1.13) and improved neurological scores (SMD: -2.3, 95% CI: -2.85, -1.76). The median score on the CAMARADES checklist was 5.5/10 (IQR 4.25-6). In particular, reporting of blinding (50%) and randomisation (35%) was low. There was pronounced asymmetry in the funnel plots of both lesion volume and neurological score data indicating publication bias. Furthermore, trim and fill analysis estimated there were 25 unpublished studies reporting negative or neutral lesion volume data which, when adjusted for, reduced the effect size to -0.40 (95% CI: -1.57, 0.77).

CONCLUSIONS: Biomaterial-based interventions decrease brain damage and promote recovery in pre-clinical stroke models. However, it should be noted there is a high risk of publication bias and there were limitations in study design including lack of blinding. We believe this study provides valuable insight to preclinical researchers interested in developing biomaterial-based interventions and informs on future directions for the translation of such therapies to the clinic.
Influence of hypoxic environment on mesenchymal stem cell pro-angiogenic and immunomodulatory profile

INTRODUCTION: Along with their differentiation potential, mesenchymal stem cells (MSCs) are thought to exert regenerative effects through immunomodulation including the ability to control inflammatory responses during tissue damage. Pre-seeding MSCS into 3 dimensional (3D) scaffolds may promote immune cell chemoattraction and would effectively provide localized control of inflammation and improve wound healing [1]. Low oxygen (O₂) concentration plays a crucial role in maintaining undifferentiated state and proliferation [2]. Taken together, we hypothesized that hypoxia might promote the immunomodulatory potential of MSCs cultured in 3D through paracrine regulation. We have previously reported that the efficiency of collagen based-medical device (Hemocollagene®) as biomimetic scaffold mimicking MSCs niche [3]. Here, the aim of this study has been to evaluate the hypoxic (3% O₂) effects on the proliferation of MSCs derived from various tissue sources and the production of cytokines and growth factors required for tissue healing.

METHODS: Human MSCs from bone marrow (BM-MSCs), dental pulp (DP-MSCs) and Wharton’s jelly (WJ-MSC) were cultured within the foam for 4, 7 and 10 days under 3% and 21% of O₂. The secretory profile of these cells was analyzed by ELISA quantification.

RESULTS & DISCUSSION: MSCs cultured in 3D secreted angiogenic factors without prior activation, such as IL-6, IL-8 and VEGF, whatever their origin. TGF-β, HGF and PGE-2 were also secreted by MSCs creating an immunosuppressive environment. In addition, neither major pro- and anti-inflammatory cytokines (TNFα, IL1-β and IL-10 respectively) nor b-FGF were detected in our experiments. 3% O₂ do not change the amount of cells containing in foams over the time, except for DP-MSCs for which a decrease has been reported. Hypoxia enhances both angiogenic and immunomodulatory capacities of MSCs. We noticed that profiles of mediators release varied according to MSCs source, the proportion of oxygen and the duration of cell culture.

CONCLUSIONS: The outcomes show that 3% O₂ for 10 days under 3D culture may enhance MSCs therapeutic effects before transplantation for cell therapy or regenerative medicine. It would be interesting to study the behavior of endothelial cells and immune cells in regard of immunomodulatory and pro-angiogenic capacities of MSC after preconditioning.

INTRODUCTION: In this study, tumor spheroids were developed within size-controlled microgels as a 3D cell culture platform via a flow-focusing microfluidic fabrication. Mechanical properties of microgels and co-culture with supporting cells were controlled to influence 3D cancer spheroid formation.

METHODS: A double flow-focusing microfluidic device coupled with photocrosslinking was used to fabricate spherical microgels encapsulated with breast cancer cells (e.g. MCF-7). For co-culture experiments, MCF-7 cells. The mechanical stiffness of microgel was controlled, with elastic modulus ranging from 0.7 to 30 kPa, by Mgel concentration. The viability, proliferation and spheroid formation of encapsulated cells were monitored over time by LIVE/DEAD assay (Thermo Fisher Scientific).

RESULTS & DISCUSSION: The MCF-7 cells encapsulated inside the microgels showed high viability throughout the cell culture regardless of the mechanical properties of microgel. However, the rate of proliferation was highly dependent on their mechanical properties; the cells proliferated faster within microgels with higher mechanical stiffness. MCF-7 cells alone did not lead to a mature spheroid within a microgel, in which all the cells form a large, compact, and well-defined spherical cell cluster, but rather a collection of smaller cell aggregates was formed regardless of the microgel stiffness. However, when MCF-7 cells were co-cultured with supporting cells, macrophages or fibroblasts, well known to be involved with tumor progression, the cells turned into a mature spheroid regardless of the microgel stiffness, though their rate and extent of spheroid formation was dependent on the microgel stiffness.

CONCLUSIONS: The 3D tumor spheroids developed in this study could be applied as platform for drug screening applications as well as fundamental biological investigation.

PRMT6 inhibits the migration ability of stem cells from the apical papilla
M. Li¹, C. Zhang², Z. Fan¹
Presenting Author: Chen Zhang, zhangchen710cool@qq.com
¹Laboratory of Molecular Signaling and Stem Cells Therapy, Beijing Key Laboratory of Tooth Regeneration and Function Reconstruction, Capital Medical University School of Stomatology, Beijing, China ²Department of Endodontics, Capital Medical University School of Stomatology, Beijing, China

INTRODUCTION: Enhanced cell homing is a basic and essential ability for dental mesenchymal stem cells to promote dental pulp regeneration [1]. Multiple studies have indicated the crucial role of PRMT6 in cells migration capacity [2-3]. Hence, we used stem cells from the apical papilla (SCAPs) to investigate the effect of PRMT6 on the migration ability.

METHODS: SCAPs at passages 3-5 were used in experiments. Real-time RT-PCR and Western blot were conducted. Scratch migration assays: SCAPs were cultured in six-well plates at a density of $2 \times 10^5$ cells/ well. Wound tracks were introduced by scraping the cell monolayer on the well with a 1000μl pipette tip (Axygen® Corning, NY, USA). Images after incubation for 24 hours and 48 hours were also taken. The upper chamber with an 8.0 μm pore size membrane (Corning, Costar, MA, USA) was seeded with $2 \times 10^4$ SCAPs. Transwell chemotaxis assays: The plate was cultured in an incubator at 37°C for 24 hours and 48 hours. The images of each well were randomly selected by using microscopy (Olympus Corporation, Tokyo, Japan) and the transferred cell numbers were counted.

RESULTS & DISCUSSION: PRMT6 was knocked down in SCAPs, as confirmed by real-time RT-PCR and Western blot. The scratch-simulated wound migration assay results showed that PRMT6 knockdown enhanced the migration ability of SCAPs at 24 hours and 48 hours. Transwell chemotaxis assay results showed that PRMT6 knockdown enhanced the chemotaxis ability of SCAPs compared with the control group at 24 hours and 48 hours.

CONCLUSIONS: Collectively, these data indicated that PRMT6 inhibits the migration and chemotaxic ability of SCAPs.

INTRODUCTION: This study investigated the ability of hypoxia-induced 25-fold concentrated conditioned media (hCM) from human nasal inferior turbinate-derived mesenchymal stem cells (hTMSC) to repair injured vocal folds in early phase of wound healing process.

METHODS: The right-side lamina propria of the vocal fold was injured in 60 Sprague-Dawley rats. Next, hCM from hTMSC (the hCM group) or hTMSC (the hTMSC group) were injected to the injured vocal folds. As a control, phosphate-buffered saline (the PBS group) or 25-fold concentrated media (the media group) was injected the in the same manner. Injections were performed twice weekly in both hCM and media group, and the vocal folds were harvested for quantitative real-time polymerase chain reaction (PCR) at 1 week and 2 weeks after injury. Histologic evaluation was done at three weeks post-injury.

RESULTS & DISCUSSION: In the hCM group at 1 week after injury. PCR showed that the gene encoding hyaluronan synthase (HAS) 1, HAS 2 were significantly upregulated compared the media and normal group. The gene encoding procollagen III was significantly downregulated compared with the media group. Nearly identical results were obtained for the hTMSC group at 1 week after injury However, the mRNA expression levels of several genes did not differ among the groups at 2 weeks after injury. Histological examination showed that the hCM group was similar or better than the hTMSC group in collagen deposition and hyaluronic acid production.

CONCLUSIONS: The injection of hCM into injured vocal folds twice per week produced an antifibrotic effect in the early phase of wound healing. The results were equivalent to those with hTMSC for up to 2 weeks. These results provide a foundation for future clinical use of hCM for vocal fold regeneration.

ACKNOWLEDGEMENTS: This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Ministry of Science, ICT and Future Planning (No. 2014R1A2A2A01004325) Korea Health Industry Development Institute funded by the Ministry of Health and Welfare (HI14C3228, HI16C0133)
Investigation of endothelial cell viability and growth on 3D printed GelMa vascular networks

¹School of Materials, University of Manchester, Oxford Road, Manchester, M13 9PL, UK

INTRODUCTION: A major limitation for the development of successful three-dimensional (3D) engineered tissues is the absence of viable and perfusable blood vessels [1-3]. 3D filament networks of pluronic were printed using the I&J 7300-LF printer, the filaments were then coated with a hydrogel (gelatin methacrylate, GelMa) forming cylindrical channels. Human umbilical vein endothelial cells (HUVECs) were cultured and lined with the hydrogel channels to consequently encourage vascularization of adipose tissue constructs.

METHODS: GelMa was synthesized using the one pot synthesis method. The hydrogel was then characterized using NMR, surface tension, contact angle and DMA. Pluronic filaments were printed using a robotic printer onto glass slides. The diffusion of substances onto the gel was also investigated by using food dyes. HUVECs were cultured on top of the GelMa substrate. Live/Dead and Alamar Blue assays were used to assess the cells’ viability and proliferation respectively. Phalloidin staining was used to assess actin cytoskeleton organization.

RESULTS & DISCUSSION: The GelMa NMR showed the changes that occurred before and after crosslinking. Furthermore due to its high hydrophilic and adhesive properties, viability assays confirmed that the cells were viable after 48 hours culture. The alamar blue data indicated an increase in cell metabolism over a 7 day period which was further complimented with a pico green assay. The pico green assay showed that there was a rapid cell number increase after 96 hrs using a standard curve equation y=mx+c. Phalloidin staining demonstrated good organisation of the actin cytoskeleton of HUVECs on GelMa.

CONCLUSIONS: Collectively, these data clearly illustrate that HUVEC cells could potentially grow and differentiate within those channels. However investigations are still ongoing.

INTRODUCTION: During in vitro stimulation of stem cells differentiation, the amount of chondrogenic factors is precisely administered from the external cell media over time. In vivo this condition cannot be replicated. The ideal chondro-regenerating bioscaffold needs to be carefully fabricated to allow the self-differentiation of stem cells laden into the biomaterial implanted in vivo [1]. We have identified a system that can be applied for the delivery of chondrogenic factors directly within the scaffold itself. This strategy consists on the fabrication of microspheres distributed homogeneously within the 3D printed bioscaffold, encapsulating the differentiating factors with a slow and controlled release across the sample.

METHODS: Alginate spheres loaded with chondrogenic growth factors TGFβ-3 and BMP-6 separately were fabricated using a microfluidic device. The release of growth factors from Chondrogenic Alginate Spheres (CAS) was tested in cell culture media for 20 days. The amount of growth factors released was quantified using ELISA tests. In vitro, CAS were tested by preparing three different concentrations of growth factors per sample (31.25, 62.5 or 125 ng/sample) incorporated within human adipose derived mesenchymal stem cells laden hydrogel material (GelMA/HAMA). DNA analysis, GAG content, gene expression (PCR) and Immunostaining analysis was performed at 0, 14 and 21 days.

RESULTS & DISCUSSION: The release profile from CAS demonstrated a controlled sustained release over 21 days. The GAG/DNA content showed a dependency on the loading concentration of the growth factors within CAS. In vitro, the CAS induced the expression of Collagen II gene after 21 days of culture. Immunostaining analysis showed collagen I and collagen II formation across all the samples treated with CAS.

CONCLUSIONS: The incorporation of CAS within a bioprinted hydrogel containing stem cells can induce chondrogenesis. This approach has the potential to drive cellular differentiation in surgically printed hydrogels in vivo.

INTRODUCTION: Various surgical techniques have been proposed for joint cartilage injuries, but regardless of the regenerative technique, securing good integration at the host–bioscaffold interface is a long-standing technical hurdle that leads to an unstable junction, unable to withstand the physiologic stresses placed across it. The eventual result is deterioration and disintegration of the attempted repair. In this work we demonstrate that in situ bioprinting and crosslinking of a chondrogenic hydrogel in an osteochondral ex-vivo model greatly improves the immediate adhesion at the host cartilage-scaffold interface.

METHODS: GelMa/HAMA hydrogel with human adipose-derived stem cells were used as chondrogenic scaffold for cartilage regeneration1 and bioprinted in human ex-vivo osteochondral defect models [Duchi et al, Tissue Eng part C, submitted for publication]. Four groups were compared: 1) Control: defect left empty; 2) Ex situ: bioscaffold pre-fabricated in a mold of the same size of the defect and implanted; 3) Ex situ + Glue: bioscaffold pre-fabricated in a mold of the same size of the defect, implanted and fixed with fibronectin glue (commercially available surgical glue); 4) In situ: bioscaffold printed and crosslinked directly in the defect, using a hand-held extrusion printer 2,3. Samples were cultured for 8 weeks in a perfusion system with chondrogenic media. We performed immunohistology with hyaline-like cartilage markers, confocal microscopy, second harmonic generation, light sheet microscopy imaging, and mechanical tests (including confined and unconfined compression test + pull out test).

RESULTS & DISCUSSION: Collagen II is accumulated in the in situ bioscaffolds after 8 weeks of chondrogenic stimulation by TGFβ-3 and BMP6. The in situ bioscaffolds presents regions of integration with the Osteochondral Unit. In the Control condition no spontaneous regeneration was present. The ex situ approach did not allow a proper implantation. In presence of Fibrin glue no evidences of lateral integration were observed. The in situ bioscaffold is better integrated with the host tissue. In situ bioprinting and crosslinking demonstrated superior adhesion to the surrounding cartilage, defined by an increased pull out resistance.

CONCLUSIONS: Surgical bioprinting can improve adhesion and integration of cartilage scaffolds, therefore solving one of the main challenges in articular cartilage regeneration.

α-TCP bone cements for bone tissue regeneration

D. Loca, M. Skrinda, Z. Irbe, J. Locs

Presenting Author: Dagnija Loca, dagnija.loc@rtu.lv

Rudolfs Cimdins Riga Biomaterials Innovations and Development Centre of RTU, Institute of General Chemical Engineering, Faculty of Materials Science and Applied Chemistry, Riga Technical University, Pulka 3, Riga, LV-1007, Latvia

INTRODUCTION: The most prospective materials for the bone tissue replacement and regeneration are calcium phosphates (CaP) due to their biocompatibility, osteoconductivity and similarity to the natural bone mineral phase. Among CaP biomaterials, CaP bone cements (CPCs) have attracted extended attention because of their ability of self-setting in vivo, moldability and injectability, opening the new opportunities for minimally invasive surgical procedures [1]. Cements based on α-TCP are expected to have intermediate resorption properties in-between stoichiometric hydroxyapatite (Ca₅(PO₄)₃OH) cements and brushite (CaHPO₄·2H₂O) cements. The reaction between water and α-TCP is slow and must be accelerated by adding the phosphate ions to the liquid phase, for cement to set in a reasonable time. The impact of α-TCP preparation method on the resulting CPC was evaluated in terms of setting time, porosity and mechanical properties.

METHODS: Two approaches were applied for an α-TCP preparation: high temperature synthesis at 1300 °C and low temperature synthesis <1000°C. The phase composition of prepared powders was analyzed using XRD, the specific surface area of α-TCP was determined using the BET method (ISO 9277:2010). The value of specific surface area found was used to calculate the average α-TCP particle size. CPC samples were prepared by mixing the α-TCP with sodium salts and setting time as well as mechanical properties and morphology of resulting CPCs were determined.

RESULTS & DISCUSSION: It was determined that high temperature α-TCP particles have irregular morphology, specific surface area of 1.5 g/m² and average particle size (calculated from BET results) of 1.38 μm. Hence the setting reaction of α-TCP is too slow for the clinical applications; phosphate salt solution was used to obtain the cement setting time of 17.5 ± 1.2 min. Impact of solid to liquid phase ratio on CPS mechanical properties was investigated and it was found that by increasing the volume of liquid phase open porosity of the samples increased, decreasing the mechanical properties of calcium phosphate bone cements from 9.61 ± 2.31 MPa down to 4.51 ± 0.38 MPa. As the particle size and surface area of the solid phase are mainly responsible for the cement final properties, low temperature synthesis of α-TCP was performed, obtained particles characterized and CPC prepared.

CONCLUSIONS: During the research it was established that by low temperature synthesis approach it is possible to obtain α-TCP particles with decreased particle size, increased specific surface area and overall reactivity.

A double-crosslinking approach for high-fidelity 3D bioprinting of cell-laden scaffolds

INTRODUCTION: Over the last decade, work on development of tissue organoids using 3D bioprinting (3DP) has been at the forefront of medical research [1]. High fidelity 3DP of cell-laden scaffolds depends on the bioink that possesses favorable physical characteristics such as shear thinning to be printable and at the same time the ability to retain its shape after printing. Here, we describe a double crosslinking approach (ionic and covalent) for 3DP of alginate (Alg) and gelatin (Gel) based bioink with phototunable mechanical properties for creating 3D engineered bone tissues.

METHODS: Human mesenchymal stem cells (hMSCs) (Lonza, Walkersville, MD, USA) were isolated from bone marrow aspirate. The cells were expanded and then mixed with the bioinks containing 0.8% Alg, 0.2% photoinitiator (Irgacure D-2959) and various Gel and methacrylated Gel (GelMA) concentrations. During printing, a lattice-rod model was extruded at the pressure of 30-50 kPa. The scaffolds were photo-crosslinked with UV for 5 min and 2% (w/v) CaCl₂ solution for 10 min. Printability, mechanical properties, in situ photocrosslinking and in vitro cell viability of Alg/Gel/GelMA bioinks were measured.

RESULTS & DISCUSSION: Rheology studies showed the shear-thinning behavior for Gel/GelMA bioinks, where inks with higher Gel concentration had more pronounced shear-thinning behavior. Addition of GelMA significantly increased the relative weight after a 14-day incubation in culture medium from 0.447±0.05 to 1.192±0.053. Compressive moduli of the double-crosslinked gels resulted in significant increase of stiffness ~20 times for 10% GelMA compared to 2.5%. Material stiffness was found to be important for cell viability. Gels with lower compressive moduli had lower number of viable cells (47%), while the stiffest gel also resulted in lower viability (63%). Formulations with 6/5 and 4/5 Gel/GelMA showed viability of around 80%.

CONCLUSIONS: In summary, these data demonstrate that combining ionic crosslinking (Alg/Ca²⁺) and covalent UV crosslinking (GelMA) can help to create more stable bioprinted constructs. It was shown that only a GelMA concentration of 5% was suitable for bioprinting purposes. Gel presence helped to modulate the viscosity and provided initial stability during the printing due to a higher gelation rate.

INTRODUCTION: Immunoregulatory features of mesenchymal stem cells (MSCs) have raised great hope for its clinical use in the treatment of various immune-mediated disorders. However, all MSCs lack molecular effectors of cell migration, thereby limiting their ability to enter inflamed tissue(s) following systemic administration. Ex vivo fucosylation of the molecule CD44 on MSCs generates the potent E-selectin ligand HCELL, enabling in vivo MSC migration to endothelial beds that express E-selectin. However, the inherent biochemical and functional properties of fucosylated MSCs has not been tested.

METHODS: In the present work we performed a direct comparison between unmodified murine adipose tissue MSCs (UmASCs) and fucosylated mASCs (FucmASCs) by analyzing: 1) cell morphology in culture; 2) proliferation kinetics; 3) MSC immunophenotype; 4) multipotent differentiation capacity; 5) secretome profile; and 6) expression of anti-inflammatory molecules.

RESULTS & DISCUSSION: UmASCs and FucmASCs displayed similar plastic adherence and a fibroblastic-like appearance typical of MSCs in culture. Both UmASCs and FucmASCs showed similar exponential cell growth curves, no significant different expression of MSC surface markers compared to UmASCs along time of culture, neither significant differences in the ability to differentiate to adipocytes, osteoblast and chondroblasts. However, we found that FucmASCs-conditioned medium contained significant greater amounts of several chemokines including KC, eotaxin, MIP-1, MCP-1 and RANTES. Analysis of expression of anti-inflammatory molecules by qPCR revealed that FucASCs expressed significant higher levels of heme-oxygenase-1 (Hmox-1), IL10, galectin-1, COX-1 and TGF compared to UmASCs. Importantly, IFN-stimulated FucmASCs showed a significant upregulated expression of HGF, Hmox-1, IDO, COX-2 and TGF compared to UmASCs.

CONCLUSIONS: Apart from their demonstrated improved migration to inflamed tissues, fucosylated ASCs displayed a significantly different secretome profile and an enhanced anti-inflammatory potency compared to unmodified ASCs, indicating that fucosylated ASCs may be a new safe and more effective cell therapy product for the treatment of immune-mediated disorders.

INTRODUCTION: Electrosprinning (ELS) is a technique used for the production of polymer based nanostructured membranes suitable for biomedical applications, in particular in the field of tissue engineering. The present work reports the production and the characterization of polycaprolactone (PCL) based membranes, implemented with a bioactive chitosan derivative (CTL) and silver nanoparticles (nAg).

METHODS: A solution of PCL 12% w/V in DCM:DMF 7:3 was electrospun for 1 h by means of a custom made device with the following parameters: 17 kV of potential, flow rate of 0.6 mL/h, 27G needle, 15 cm of distance. Scanning Electron Microscopy (SEM) was used to analyze the nanofibers and micro-Computed Tomography for the analysis of membrane thickness. An air-plasma treatment was used to expose hydrophilic groups on membrane surface, in order to adsorb CTL and CTL-nAg. Ag was quantified with Inductively Coupled Plasma Mass Spectrometry ICP-MS. Wettability and biocompatibility of membranes were tested.

RESULTS & DISCUSSION: The ELS process used in this work allowed to obtain PCL membranes with an average thickness of 215 μm and an average nanofiber diameter of 600 nm. The efficacy of CTL adsorption process was confirmed with confocal microscopy using FITC labelled CTL (Fig. 1A). Contact angle measurements showed the poor wettability of PCL membrane (as prepared), and the increased hydrophilicity of air-plasma and CTL coated membranes. Biocompatibility was tested using MG63 cells cultured on membrane surface; Fig. 1B shows that CTL-coated membranes were able to support cell adhesion and proliferation. In contrast, both as-prepared membranes and air-plasma treated membranes exhibited poor cell adhesion and proliferation.

CONCLUSIONS: The data here presented proved the hydrophilicity and biocompatibility of ELS membranes made of CTL-nAg. These data are promising for potential application such as wound healing or Guided Bone Regeneration.

Figure 1: A) Confocal microscopy image, which shows the fluorescence of CTL-FITC adsorbed on PCL nanofibers. B) SEM micrograph of MG63 cells, which proliferated for 7 days on the surface of CTL coated PCL membrane.

ACKNOWLEDGEMENTS: Financial support was received from University of Trieste fund program: FRA 2016. The authors thank Dr. Denis Scaini (SISSA, Trieste, Italy) for his help with air-plasma and Dr. Matteo Crosera (University of Trieste) for his kind support with ICP-MS.
Development of 3D Tumour Models for Ameloblastoma

D. Bakkalci¹, S. Fedele¹,², U. Cheema¹,²
Presenting Author: Deniz Bakkalci, deniz.bakkalci.16@ucl.ac.uk
¹Division of Surgery and Interventional Sciences, University College London (UCL)

INTRODUCTION: Ameloblastoma (AM) is a rare odontogenic neoplasm, which is associated with bone resorption (1, 2). The underlying mechanisms of how bone destruction occur are not well known. Aim of this project is to develop a 3D tumour model for ameloblastoma to look at possible bone resorption mechanisms.

METHODS: Ameloblastoma cells (AM-1 and AM-3 cells) and osteosarcoma cells (MG-63) were cultured using RAFT™ 3D Cell Culture system. 50,000 cells for each cell line were seeded per ACM. The gels were compressed via RAFT absorbers to remove excess fluid. To measure invasion distance and determine invasion patterns, images were taken for Day 1, 7, 14, and 21 at four different positions (Figure 1). The tumouroids were stained for Immunofluorescence imaging for different time points. Invasion represents invading the surrounding stroma from ACM, thereby, invasion is the distance from stroma.

RESULTS & DISCUSSION: Previously, it was reported that highly metastatic cancers invade aggressively to the surrounding stroma within tumouroids. (3) showed that, a highly metastatic colorectal cancer cell line HCT116 was found to invade as cell sheets. MG-63 and AM-1 cells also showed the similar sheet pattern. Exclusive invasion of MG-63 can be due to the fact that its association with poor prognosis upon metastasis and recurrence of the disease (4). (3) also highlighted that a less metastatic colorectal cell line HT29 invades limited distances due to its invasion pattern. Similar to HT29, AM-3 cells form bud-shape cell aggregates around ACM and invades to stroma by keeping this shape. When invasion distances of AM cells and MG-63 cells were compared over 21 days, AM-1 and MG-63 cells can invade greater distances than AM-3. This might be due to cell sheet invasion pattern as both AM-1 and MG-63 cells have the same pattern. Whereas, AM-3 cells tend to form cell aggregates budding out from ACM and these aggregates are conserved for 21 days.

CONCLUSIONS: 3D tumour models enables to investigate cell characteristics, future works will focus on the association between ameloblastoma cells and proteins involved in bone resorption.

INTRODUCTION: The isolation and trans-differentiation of salivary gland stem cells (SGSCs) could be of critical for salivary gland- or other glands’ regeneration in case of pathology. Recently, stem cells from major salivary glands were reported to trans-differentiate to other cell lines including hepatocytes [1-3]. This study aims to investigate the capacity of SCs derived from human minor salivary gland (mSGSCs) to trans-differentiate to b-cells of pancreas.

METHODS: mSGSCs from the lip were isolated and characterized using mesenchymal, epithelial and stem cell biomarkers by flow cytometry. Cells were cultured in DMEM/F-12 medium, supplemented with 10% FBS, antibiotics / antimycotics, in addition to activin-A, retinoic acid and GLP-1 (glucagon-like peptide1). The gene expression of pancreatic transcriptional factors Pdx1 (pancreatic duodenal homeobox factor-1), Ngn3 (neurogenin 3), Pax4 (paired box 4) and Nkx6.1, pancreatic SCs markers including c-Met (HGF receptor) and carbonic anhydrase II, as well as insulin, Glut2 (glucose transporter 2) and AFP (alpha-fetoprotein) was evaluated by Real time RT-PCR.

RESULTS & DISCUSSION: MSGSCs expressed embryonic stem cell marker SSEA-4 (32.6 %), mesenchymal markers CD90/Thy1 (92.9 %), CD105 (86.4 %), nestin (84.9 %) but not hematopoietic markers CD34 (1.9 %) or CD45 (1.4 %), and epithelial markers cytokeratins (CK) 14 (66.0 %), CK 7/8 (53.9 %), and CK 18 (26.3 %). Microscopically, a mixed population with fibroblast-like cells (majority) and only few epithelial-like cells was observed. This mixed population strongly expressed pancreatic transcriptional factors Pdx1 and Nkx6.1, as well as pancreatic stem cell markers (c-Met and carbonic anhydrase II).

CONCLUSIONS: For the first time stem cells derived from human minor salivary glands from oral mucosa, an easily accessible source of stem cells, were able to differentiate towards cells expressing pancreatic transcriptional factors and pancreatic stem cells markers. This provides a promising strategy for their autologous application in pancreatic regeneration of Type II diabetic patients.

INTRODUCTION: Avascular necrosis of the femoral head (ANFH) is accompanied by severe pain and results in gradual failure of the femoral head and substantial joint function disorder. We defined the following purposes of an experimental study: (1) to develop a regenerative medicine technology for the surgical treatment of ANFH with use of 3D tissue-engineered osteoprogenitor equivalent/graft (3D-OPG) based on autologous bone marrow-derived multipotent mesenchymal stromal cells (BM-MSCs) and fibula-derived periosteal progenitor cells (PPCs) seeded within bone chips, as applied to disease stages III-IVC; (2) to assess the safety of surgical treatment and its effect on pain in the hip, the functional state of the hip joint, and the anatomical condition of the femoral head in the near and distant post-treatment timeframes. The purpose of the analysis was to assess in retrospective the clinical outcomes of 26 patients aged 21 to 52 years who were treated with use of 3D-OPG during 2004-2013 in two hospitals in Ukraine.

METHODS: For cell and bone equivalent manufacturing, tissue engineering and cell culture methods were applied. For clinical results’ assessment the X-ray and MRI examinations were used.

RESULTS & DISCUSSION: After completion of treatment with the use of 3D-OPG, all patients either had no pain or reduced pain (p = 0.001). Six months after the completion of treatment, 36% of patients had no pain, 52% had pain after a long-term load on the joint and 12% after a minor load. After 5 years, 24% of patients had no pain, 52% had pain after a long-term load, 20% after minor load, and in one patient (4%), pain occurred within 10 min after imposition of the load. The functional state of the joint in all patients was better than before treatment (p = 0.001) for the entire observation period. After 6 months, 64% of patients were able to function independently. By the end of the fifth year, 72% of patients were able to function independently, while one patient (4%) required constant external help. Six months after the authorization of a full load on the joint, 36% had no increase in the deformation of the head; 52% had a slight (less than 5%) deformation. In the remaining 12%, this deformation did not exceed 10%. After 5 years, the deformation of the head had not increased in 24%; in 52% head deformation exceeded 5% and in one patient (4%) the deformity of the head had increased by more than 10%. By the end of the fifth year follow-up, 56% of patients had good results, 40% had satisfactory results, and one (4%) had poor results.

CONCLUSIONS: The surgical treatment of ANFH III-IVC, according to our original 3D-OPG technology, was revealed to be safe and effective. This provided therapy reduces the severity of pain (p = 0.001), improves the functional condition of the hip (p = 0.001), allows the arrest of the process of bone tissue destruction in the femoral head [1].

INTRODUCTION: Human endometrium is a new potential source for MSCs isolation due to significant regenerative potential and ability to full self-renewal throughout the woman's reproductive life [1, 2]. However, the potential therapeutic use of endometrial MSCs (eMSCs) evokes a number of challenges, e.g. ex vivo cell large-scale expansion under xeno-free conditions with use of platelet lysate (PL).

METHODS: Endometrium samples were obtained from 5 donors with endometrial hypoplasia (34 ± 3.3 years) by pipelle sampling in a proliferative phase. Patient’s voluntary informed consent was signed. The endometrium biopsies were dissociated by enzymatic method. To study the immunophenotype and cytokine production cell cultures at P3 were used. The PDT value was assessed at P3, using standard formula. There was control versus two culturing condition groups of comparison (2% PL vs 5% PL).

RESULTS & DISCUSSION: It was observed a significant difference between the control group and 2% PL group. However, the PDT values in the groups of control and with 5% PL were comparable. The analysis of the typical MSC immunophenotype did not reveal a significant difference by markers (CD90+ CD105+ CD73+ CD34- CD45- HLA-DR-), both in the control and in PL groups. An increase in the expression of CD140a in the comparison groups against the background of reduced CD166 expression was observed to the control group. The expression of CD140b, CD146 were maintained at a consistently high level, while CD106 CD184 CD271 CD325 were expressed at a low level. Expression levels of SUSD2, ESR-1 and PGR were comparable in PL groups. Although the expression level of ESR-2 increased in 2% PL group. High levels of growth factors’ expression were observed in the control and 5% PL groups, when in 2% PL group it was consistently low. The functional analysis of eMSCs showed the basal level production of IL-1ra, IL-8, IL-9, IL-10, IL-15, IL-17, FGF, G-CSF, GM-CSF, IFN-β, MCP-1, TNF- α in all groups. The production of IP-10 was significantly reduced in experimental groups in comparison with a control. It should be noted that in the group with 2% PL it was observed the highest level of IL-6 and eotaxin production. Production of VEGF, PDGF-bb, RANTES, IL-12 was increased in dose-dependent manner in PL groups.

CONCLUSIONS: Cultured under xeno-free conditions eMSCs meet minimal ISCT criteria [3]. Their proliferative potential and secretome profile make them a perspective object for use in regenerative medicine.

Hybrid scaffold to anterior cruciate ligament regeneration
D. Kolbuk-Konieczny¹, O. Urbanek-Swiderska, O. Jeznach¹
Presenting Author: Dorota Kolbuk-Konieczny, dkolbuk@ippt.pan.pl; dorotakolbuk@gmail.com
¹Institute of Fundamental Technological Research Polish Academy of Sciences, Laboratory of Polymers and Biomaterials, Warsaw, Poland

INTRODUCTION: Anterior cruciate ligament rupture is one of the main injuries of sportsmen and young people. Despite the relatively long time of recovery, professional footballers cases indicate that after 3 years from the end of treatment, only 65% of the players returned to professional activity [1]. The aim of this poster is to show hybrid scaffold which is able to regenerate ligament and regenerate bone in which it is fixed.

METHODS: Different types of polyesters nonwovens were formed by electrospinning. Their surface was modified with growth factors and hydroxyapatite. Scaffold morphology was illustrated by SEM (scanning electron microscopy); chemical structure was evaluated by FTIR (Fourier-transform infrared spectroscopy) and EDS (energy dispersive spectroscopy). In-vitro cellular studies were carried out on fibroblasts and osteoblasts. Cellular morphology was analyzed by SEM and FM (fluorescence microscopy); cytotoxicity and proliferation were determined by MTT and Presto Blue test respectively.

RESULTS & DISCUSSION: FTIR and EDS data confirm effectiveness of chemical modification. SEM illustrates hydroxyapatite nanoparticles on electrospun fibres surface (Fig. 1). Cell culture studies demonstrated that the fibroblasts are spread on the nonwovens, they indicate proper morphology in comparison to cells seeded on TCP (tissue culture plastic - control) (Fig. 2). Cytotoxicity test indicates nontoxic character of nonwovens before and after modification; cellular proliferation is higher on nonwovens modified by TGF and BMP growth factors.

CONCLUSIONS: Nonwovens modified by growth factors and hydroxyapatite enhance cellular spreading, migration and proliferation due to similarities to natural extracellular matrix in chemical and morphological properties.

Figure 1: (left) Nonwovens morphology before (a) and after HA (b) coating. Figure 2: (right) Morphology of cells seeded on a) TCP, b) PLGA with TGF, c) PLCL with RGD d) PLCL with TGFβ. Images were collected with FM.

Mathematical modeling of magnetically targeted stem cell delivery
E. Yeo¹, H. Markedies², J. Oliver¹, A. El Haj ², S. Waters¹,
Presenting Author: Edwina Yeo, yeo@maths.ox.ac.uk
¹Mathematical Institute, University of Oxford ²University of Birmingham, Birmingham

INTRODUCTION: In stem cell therapies used in regenerative medicine a key challenge is to deliver the cells to the site of injury. One approach is to label cells with magnetic particles and use externally applied magnetic fields to guide the cells to the target site. To optimise delivery protocols it is essential to understand the interplay between the fluid mechanics, magnetic fields and stem cell properties. We develop mathematical models alongside in vitro and in vivo experimental models to provide mechanistic understanding.

METHODS: Magnetic nanoparticles (MNPs) are utilised to tag mesenchymal stem cells (MSCs) which can then be targeted using an external magnetic field. This was carried out in vivo and in vitro. In vitro we used a custom model and MSCs in concentrations of red blood cells (RBCs) from 0% to 40% for various flow rate and degrees of magnetic tagging. This has shown that magnetic tagging increases trapping, with a trapping of up to 31% (versus 17.5% for untagged cells) in a blood concentration of 40% [1]. In our mathematical model we have assumed steady fully developed Poiseuille flow in the pipe. The magnetically tagged MSC experiences Stokes drag from the fluid and a magnetic force [2]. Haematocrit is included through modifying the viscosity of the fluid. We have computed trajectories of cells in the pipe as a function of the initial position, flow rate, magnetisation of the particles and properties of the fluid.

RESULTS & DISCUSSION: Mapping the flow theoretically we have been able to predict deposition of stem cells on the vessel wall. The model reproduces the damping effect of RBCs on capture of stem cells. Realistic magnetic fields allow us to quantify effect of magnet strength and geometry on capture of stem cells.

CONCLUSIONS: Mathematical models can allow us to gain cheap and quick insights into potential treatments. This can allow the rapid exploration of parameter space, calculating optimal regimes for trapping as well as the boundaries the space where capture is feasible. Through this model we can predict the optimal flow rate and minimum magnetic field strength required for a desired percentage of trapping. This model can be readily adapted to include variability in tagging with MNPs, whereas current studies have assumed heterogeneity of tagging. It also offers the flexibility to include time dependent effects such as pulsatile fluid flow or the extravasation of cells.

INTRODUCTION: Large regenerating tissues (100–200μm) show limited nutrient supply and waste removal capacity by diffusion, and thus they require an intimate supply of vascular networks. Vascularization from the surrounding tissue however, is a slow process and therefore, it remains a critical obstacle in engineering multicellular, metabolically demanding organs. Since Endothelial (ECs) and Mural (MCs) cells are the cellular components of blood vessels and their interactions are crucial for neovascularization, both cell types and their arrangement into correct spatial organization are needed in order to rescue tissue engineered constructs from critical ischemia and to form a functional vascular network in vivo. Based on this context and in order to overcome the limitations concerning the isolation and expansion of human MCs, we initially induced the differentiation of human pluripotent stem cells (hPSCs) to MCs. hPSCs-MCs were then co-grafted with hECs as 3D vascular units (VUs) into a matrix to rapidly give rise to a complex three-dimensional functional network of human neovessels in vivo.

METHODS: We developed a simple, efficient and rapid strategy to induce the differentiation of human PSCs to defined MC populations (contractile and synthetic hPSCs-MCs) by using feeder-free and low serum conditions in vitro. Cells were extensively characterized concerning their phenotype (expression of CD44, CD73, CD105, NG2, PDGFRβ, aSMA, calponin, SM22α, SMHC) and function. We generated then VUs (spheroids), consisting of 1000 cells (hECs and hPSCs-MCs) using a methylcellulose-based (MC) hydrogel system. VUs were extensively characterized regarding cell phenotype and cell-cell interactions and their ability to form a three-dimensional capillary network in vitro as well as in vivo (matrigel plug assay). Furthermore, we explored the vascularization potential of these units, when they were embedded in hydrogels composed of defined extracellular components (collagen/fibrinogen/fibronectin), which could be used as scaffolds for tissue engineering applications.

RESULTS & DISCUSSION: hPSC-MCs were phenotypically and functionally stable for at least 8 passages whereas they could stabilize vessel formation and inhibit vessel network regression, when co-cultured with hECs in vitro. Furthermore, hECs/hPSCs-MCs spheroids served as focal starting points for the sprouting of capillary-like structures in vitro, using defined matrices with variable concentration and different fragments of extracellular matrix components. Finally, VU hECs/hPSCs-MCs delivery in vivo led to rapid generation of a complex functional vascular network.

CONCLUSIONS: We developed a robust method for the generation of defined hMCs phenotypes from hPSCs. Fabrication of hECs/hPSCs-MCs VUs embedded in chemical defined matrices is a significant step forward in tissue engineering and regenerative medicine.
Controlled release gentamicin delivery systems for bone regeneration applications
D. Loca, E. Tracuma, J. Locs

INTRODUCTION: For the treatment of musculoskeletal disorders, traumas and diseases a large number of highly efficient tools including load bearing metallic implants, numerous calcium phosphate bone regenerative materials and various antimicrobial agents are available on the biomaterial market and are widely used in the clinical practice. Although calcium phosphate bone cements are osteoconductive [1] and could be used through minimally invasive surgical procedures, it carries potential inflammation and bone infection risks, usually precluded through systemic antibiotic therapy. The conventional treatment requires much higher drug doses, that could be overcome by prolonged local antibiotic drug delivery [2]. Gentamicin sulphate (GENTA), is commonly used antibiotic as a vehicle for drug delivery, it has a wide antibacterial spectrum against gram-negative and gram-positive bacteria with a minimum inhibitory concentration (MIC) of ~ 0.5 μg/ml [3]. The aim of the current study is to develop the method for the preparation of GENTA containing microparticles able to release the active ingredient for 14 days, possessing MIC of ~ 0.5 μg/ml. For this purpose, GENTA was microencapsulated in poly-L-lactic acid (PLA) matrix through 3 different emulsification routes.

METHODS: Microcapsules were prepared by water-in oil-in water (W1/O/W2) double emulsion technique using three different emulsification approaches: mechanical mixing, high speed homogenization and ultrasound homogenization. Prepared GENTA/PLA microcapsules were evaluated towards total drug content, repeatability of the microencapsulation process, drug encapsulation efficiency, microcapsule average size distribution as well as drug release profiles in vitro.

RESULTS & DISCUSSION: Analysis of the prepared microcapsules showed that upon encapsulation of GENTA in the PLA matrix it is possible to obtain microcapsules in which the total GENTA content equals up to 5.5 ± 0.4 wt.%, the encapsulation efficiency of the active ingredient reaches 50%, and the average microcapsule size (d50) are in the range from 4.27 ± 0.02 μm to 220 ± 36 μm.

CONCLUSIONS: During the research it was established that emulsification approach significantly affected not only the active substances mean particles size and total drug load, but also facilitated the preparation of drug delivery system with variable and controllable GENTA delivery profile.

INTRODUCTION: Commercial bovine xenografts are used for hard tissue augmentation in dentistry for various indications. However, very little is known about how these materials result in bone formation. In this study we have compared two commercially available and a novel bovine xenograft in a series of in vitro experiments to assess their biological characteristics claimed to impact osteoconductivity.

METHODS: Two commercially available xenografts, Bio Oss (BO, Geistlich Pharma AG, Wolhusen, Switzerland), creos xenogain (CXG, Nobel Biocare, Göteborg, Sweden) were compared with a novel xenograft (HA, Wishbone SA, Belgium). Physical properties including surface area and porosity of the materials were measured with BET. Dissolution of the materials were investigated with DMEM cell culture medium supplemented with 10% fetal bovine serum (FBS) in cell culture plates. The total & mono protein adsorption were compared with FBS and albumin. Chemotaxis of cells was investigated with macrophage cell lines, RAW 264.7 cells in a Transwell chamber (Corning, USA) while cell proliferation, differentiation was investigated with 1 x 10⁵/ cm² murine osteoprogenitor cells, MC3T3-E1 cells for total period of 7 or 14 days.

RESULTS & DISCUSSION: HA material showed significant differences in comparison with BO & CXG (Table 1). The surface area of BO was significantly higher than CXG and HA (p < 0.05). Total protein adsorption and albumin adsorption illustrated significant increase (p < 0.01) in HA in comparison with BO at time periods of 1and 4 days. BO & CXG chemotaxis assay revealed significant number of macrophages in the BO & CXG group compared to the HA group.

CONCLUSIONS: The protein adsorption, progenitor cell proliferation & differentiation data clearly indicates the importance of unique surface properties in dictating the cascade of events leading to osteoconductivity in xenografts. Further in vivo studies are needed to identify whether these differences impact the material osteoconductivity in the clinical setting.

Medical Center, Rotterdam, the Netherlands

**INTRODUCTION:** Matricryptins are biologically active extracellular matrix fragments produced
by limited proteolysis [1]. Recently, three peptides derived from the Cartilage Oligomeric Matrix
Protein (COMP) were found to be secreted by wounded zones of cartilage into synovial fluid [2].
Here we asked if any of the three peptides could be involved in the regulation of specific aspects of
joint regeneration. For this purpose, we tested the peptides in vitro for known functions of the COMP
C-terminal domain from which they derive: TGFβ signaling,vascular homeostasis and inflammation
[3].

**METHODS:** Peptides were produced by chemical synthesis [Peptide2.0, Brookfield], and used
separately at a concentration of 100 nM. In order to test if any of the three peptides could modulate
the TGFβ signaling pathway, primary MSCs in monolayer were stimulated with either 0.1 ng/ml
TGFβ3 or 100 ng/ml BMP2, with or without the peptides for 24h. Then, the expression of downstream
target genes of TGFβ (COMP) and BMP2 (MSX2) was measured by qPCR. Angiogenesis was
assessed by tube formation assay. In short, endothelial cells (HUVECs) were seeded on 96 well plates
coated with reduced growth factor basement membrane [Geltrex] in combination with the peptides.
After 24h, tube-like structures were imaged and quantified. Finally, synovial explants obtained from
knee replacement surgeries were cultured in presence of the peptides for 48h and the expression of
the enzymes MMP1, MMP3, MMP13, ADAMTS4 and ADAMTS5 was assessed by qPCR.

**RESULTS & DISCUSSION:** None of the peptides affected the downstream expression of target
genes of BMP2 and TGFβ3 (p>0.05). We observed no effects of the peptides in the tube formation
assay (p>0.05). No differences on the expression of synovial catabolic enzymes were found when
peptides were added to the culture medium (p>0.05).

**CONCLUSIONS:** Joint homeostasis does not appear to be regulated by the peptides tested, at least
on the concentrations and assays tested.

INTRODUCTION: 3D Bioprinting is a revolutionary technology for the bottom up fabrication of human tissue and organs [1]. The use of biocompatible inks in 3D Bioprinters enables the rapid manufacturing of 3D tissues and organs in vitro and the precise control over microarchitecture and functionality of cell-laden constructs. The printing versatility of bioinks together with living cells diminishes the risk for poor cell viability and cell accessibility throughout the 3D network. A typical bioink consist of cells mixed with hydrogels to generate a good distribution of cells inside the 3D scaffold. Here we summarize examples of cell instructive bioinks prepared with chemically modified cellulose nanofibrils (CNFs) [2]. The CNFs were bioconjugated covalently with a cell adhesive peptides (RGD) and laminin (LN521) in order to promote human dermal fibroblast adhesion and viability in the scaffolds.

METHODS: CNF-based inks modified with the tripeptide Arg-Gly-Asp (RGD) (CNF-RGD) have been investigated and compared with CNF-Alginate ink in terms of 3D printability. The CNF-Alginate and NFC-RGD inks were mixed with alginate and Human dermal fibroblasts and 3D bioprinted in grid architecture with a 3D Bioprinter. After bioprinting the hydrogels were crosslinked in a 100 mM CaCl2 solution. Cell viability and morphology was investigated.

RESULTS & DISCUSSION: The RGD peptides were coupled to the CNFs covalently. The formulations of the bioinks were evaluated in terms of reology, printability and cross-linkability. CNF-Alginate and CNF-RGD demonstrate analogous rheological properties when measuring shear rate-viscosity. The results showed that the adhesion, viability and proliferation of fibroblasts were promoted significantly in the 3D constructs bioprinted with RGD modified bio-inks. Improved cartilage-like formations were achieved in the laminin LN521-CNF/Alginate bioinks after two weeks of differentiation of human-derived induced pluripotent stem cells (iPSCs).

CONCLUSIONS: The RGD peptides and LN521 were succesfully conjugated to the nanofibrils with various charge densities. The rheological performance and printability of the bioinks were ideal to be printed in 3D printer.

INTRODUCTION: The present work relies on the development of a conductive nanocellulose-based ink for the 3D printing of neural guidelines. Reentrant ventricular arrhythmias (VA) is a major cause of sudden death in patients with structural heart disease. Current treatments focus on electrically homogenizing regions of scar contributing to VA with ablation or altering conductive properties using antiarrhythmic drugs. The high conductivity of carbon nanotubes may allow restoration of conduction in regions where impaired electrical conduction results in functional abnormalities. We propose a new concept for arrhythmia treatment using a stretchable, flexible biopatch with 3D printed pattern with electrically conductive inks to restore conduction across regions in which activation is disrupted.

METHODS: Carbon nanotube patches composed of nanofibrillated cellulose CNF/single-walled carbon nanotube (SWCNT) ink 3D-printed in conductive patterns onto bacterial nanocellulose (BNC) sheets were developed and evaluated for conductivity, flexibility, and mechanical properties. The patches were applied on 6 canines to epicardium before and after surgical disruption. Electro-anatomical mapping (EAM) was performed on normal epicardium, then repeated over surgically disrupted epicardium and finally with the patch applied passively.

RESULTS & DISCUSSION: We developed a 3D printable carbon nanotube ink complexed on bacterial nanocellulose that was expressable through 3D printer nozzles, electrically conductive, flexible, and stretchable. 6 canines underwent thoracotomy and, during epicardial ventricular pacing, mapping was performed. We demonstrated disruption of conduction after surgical incision in all 6 canines based on activation mapping. The patch resulted in restored conduction based on mapping and assessment of conduction direction and velocities in all canines.

CONCLUSIONS: We have demonstrated that 3-D custom printed electrically conductive patches with carbon nanotube inks can be surgically manipulated to improve cardiac conduction when passively applied to surgically disrupted epicardial myocardium in canines.
Design and development of a melt electrowritten in vitro radial migration assay
E. Bakirci¹, O. Dahri¹, E. Cebellos¹,², A. Hrynevich¹, J. Groll¹, N. Schäfer², C. Villmann², P. D. Dalton¹

INTRODUCTION: In vitro models are essential for biomedical research since they provide an insight into cell behavior in a controlled environment. Several studies have been dedicated to establish an in vitro 3D neuronal model but the use of such experimental models remains limited [1]. Mimicking the physiological environment in in vitro studies has been always a challenging issue for the scientific community. Recent advances in additive manufacturing technologies, however, could improve and result in more accurate in vitro models. This study establishes a melt electrowritten (MEW) 3D culture system to monitor neural cell migration which allows simultaneously to test the effect of different hydrogels on cell and neurite migration.

METHODS: In vitro culture systems were melt electrowritten directly onto freshly prepared 6-arm, NCO-terminated star-shaped poly(ethylene oxide-stat-propylene oxide) (sP(EO-stat-PO))-coated glass slides as previously described [2]. This adhered the poly(ɛ-caprolactone) (PCL) fibers (Purasorb PC-12) to the slide and permitted numerous washing steps associated with in vitro culture. The MEW structure, printed in a radial shape, includes 8 different chambers in which specific hydrogel formulation can be dispensed and a central cell depot. Different Matrigel concentrations were dispensed into each chamber, and mouse dorsal root ganglia (DRG) loaded into the cell depot. Radial migration was monitored at 3 different time points for 7 days. The mechanical behavior of different matrix concentrations was tested with a rheometer.

RESULTS & DISCUSSION: The PCL fibers strongly adhered to the NCO-terminated sP(EO-stat-PO)-coated slides and allowed extensive printing parameter and design reiteration. The sealing of the various chambers was determined through the use of added dyes (Figure 1). The system was investigated from the visualization perspective for DRG cell migration into the different matrices. The impact of the height, dimensions and printing design on the feasibility of the radial migration assay was performed.

CONCLUSIONS: The design and development of a 3D radial migration assay is presented that combines MEW with reactive macromers and a selection of matrices so that multi-combinatorial approaches can be assessed for cell or neurite migration.

INTRODUCTION: The demand for more bioactive and biocompatible materials for orbital floor repair is increasing tremendously. Therefore, alloplastic materials are attracting attention worldwide. PU/HA composite has been introduced in the material science as a promising material for biomedical applications. Few investigations have been carried out to identify the effectiveness of such materials for bone regeneration, but little attention has been paid to the biodegradable polyurethane for orbital floor regeneration.

METHODS: The materials used were Poly-ester-urethanes (Avalon 85AB), dimethylformamide (DMF) and Commercial HA (P218R). The HA was heat treated at 750, 950 and 1100 C° respectively. The PU solutions were obtained by 10 wt% PU in DMF. 25wt% HA powders were added to PU solution to obtain PU/HA solution. Particles leaching method was used to synthesize porous scaffolds by mixing salt particles with both PU and PU/HA solution in ratio of 0.6 ml/1 g respectively, and solvent casted (evaporated) at 37 C°. Moreover, the scaffolds were characterised using FTIR (ATR and PAS), Mechanical testing (tensile), SEM and cell viability.

RESULTS & DISCUSSION: Chemical characterization confirmed the presence of HA in composite scaffolds while ATR confirmed the significant amount of HA at the scaffolds top surface. The spongy reaction of scaffolds under pressure and SEM micrographs confirmed the pore interconnectivity. The 25% scaffold survived more in tensile test compared to PU one. However, cell viability (using MG63) did not show significant difference between PU and PU/HA scaffold. Additionally, the heat treated HA (750 C°) showed significant difference in the cell viability results.

CONCLUSIONS: The porous PU and PU/HA scaffold with active and non-active surface was obtained. PU/HA scaffolds could be better for orbital floor repair due to the tensile test results. Moreover, CAM assay showed promising results with PU and PU/ HA which demonstrate potential to induce angiogenesis. Heat treated HA (750 C°) could be the most suitable choice regarding the results of cell viability.

ACKNOWLEDGEMENTS: Financial support was provided by King Khalid University; Ministry of Education; Kingdom of Saudi Arabia. Cell Viability test was conducted in Kroto Research Institute; Sheffield University.

INTRODUCTION: Skin plays an important role in protecting and supporting the body in life time. The epidermis is composed of various functional layers, which are mainly characterized by the keratinocyte properties. During epidermal development, proliferative keratinocytes in a single layer give rise to multiple differentiating layers to provide skin surface. Controlling keratinocyte adhesion, migration, proliferation and differentiation is crucial for skin homeostasis. Signaling pathways play significant roles in the various stages of epidermal differentiation. In the present study, we discussed the signaling pathways and molecules involved in epidermal differentiation.

METHODS: Original research articles about cell differentiation signaling pathways of the keratinocytes were searched in the PubMed, Cochrane and google scholar databases from 2010 to the end of 2018.

RESULTS & DISCUSSION: The signaling pathways Notch, WNT and TGFβ play an important in the process of keratinocytes differentiation through their various kinases, phospholipases and critical molecules [1-3]. The TGF-β superfamily dose dependently induces stem cells to have keratinocyte fate. Notch signaling pathway takes part in a number of major developmental decisions, promotes keratinocyte differentiation and down regulates their proliferation. On the other hand, Wnt signaling pathway suppresses the differentiation of epidermal keratinocytes via activation of β-catenin.

CONCLUSIONS: There are several signaling pathways involved in keratinocyte differentiation of stem cells. However, the selection of these signaling pathways depends on the type of stem cells, cross-talk between the signaling and the special temporal effects of the key molecules of signaling cascades.

INTRODUCTION: Bone morphogenetic proteins (BMP) functions exist in both vertebrates and invertebrates and play important roles in developmental processes such as cell proliferation, differentiation and apoptosis. BMP signaling is involved in different stages of nervous system development. In the early stages of development, BMP inhibition is required to create neuroectoderm. However, at later development stages, BMP signaling are required for specifically induction of neurogenesis, migration of neural cells and the spinal cord patterning [1-3]. The objective of this study was to evaluate the cross-talk of BMP signaling with the pathways involved in neural differentiation.

METHODS: A review of literature was conducted to identify studies regarding cross-talk of BMP signaling with other signaling pathways in regulation of neural differentiation. Databases used for finding the articles included PubMed, Google Scholar, MEDLINE and EMBASE.

RESULTS & DISCUSSION: Neural induction might have more complexity than simple inhibiting BMP signaling. Additional signals FGF, Notch, SHH and WNT signaling pathways are involved in the specification of neural fate. A key regulatory mechanism involved in neural induction is the inhibition of BMP signaling. The other mentioned signaling pathways display additional regulatory influences through BMP-related mechanisms for commitment to neural lineage.

CONCLUSIONS: BMPs signaling can induce either neurogenesis or glial differentiation at different stages of embryonic development that depend on source and the age of the target cells. The proper functioning of the BMP pathway depends on its constitutive and extensive communication with other signaling pathways, leading to synergistic or antagonistic effects and eventually desirable biological outcomes.

INTRODUCTION: The objective of tissue engineering is the synthesis of bioengineered tissues for clinical use. A requirement for these tissues is biocompatibility, and these structures should induce no inflammatory response once implanted in a living tissue. In addition, bioengineered tissues should be biomimetic and fulfill a series of biomechanical properties. New biomaterials have recently been developed by combining techniques such as nanostructuration and cross-linking applied to fibrin-agarose hydrogels. The main objective of this work is to analyze the in vivo biocompatibility of these biomaterials subjected to cross-linking techniques in order to increase their biomechanical properties.

METHODS: Fibrin-agarose hydrogels (FAH) were treated with the cross-linking agent Genipin at 0.1% and 0.2%. Native FAH and crosslinked FAH (FAH-GP) were subcutaneously implanted in 5 adult mice and results were analyzed after 12 and 26 days of in vivo follow-up. For histological analysis, animals were perfused with 10% formalin solution and post-fixed in the same solution for 24 h, dehydrated and embedded in paraffin. 5 µm thickness sections were stained with hematoxylin-eosin (H&E) for histological evaluation. PAS histochemical analyses were carried out to evaluate the glycogen content of each tissue, whereas picrosirius red histochemistry was used to identify collagen fibers in the analyzed samples.

RESULTS & DISCUSSION: We observed an initial inflammatory response in all the experimental groups (FAH, FAH-GP 0.1% and FAH-GP 0.2%). This reaction was moderate and showed a predominance in lymphoplasmacytic cells after 12 days. After 26 days, an increase in the involvement of macrophages was found, coinciding with an evident biodegradation of the FAH and FAH-GP 0.1% biomaterials. However, FAH-GP 0.2% implants did not tend to biodegradation at both evaluation times. No complications such as infection signs, necrosis or granulomas were detected in any of the groups.

CONCLUSIONS: In vivo evaluation of the biocompatibility of these biomaterials is essential in order to foresee their future performance in the human body. Our results suggest that these tissues are safe once grafted in vivo, which a minimum initial inflammatory reaction, and support the future clinical application in regenerative medicine protocols.

INTRODUCTION: The goal of skin tissue engineering is to produce functional artificial skin tissues able to reproduce the biological functions of this organ. The mechanical properties of these skin substitutes should mimic the properties of the native human skin in order to provide its required anatomical and physiological functions. In this context, analysis of the mechanical properties of artificial skin substitutes is of great importance in the context of the quality control analyses of these bioengineered organs. Ensuring that the mechanical properties of these products are similar to the native skin is essential before clinical use [1, 2]. The purpose of this study was to perform a biomechanical analysis of human artificial skin substitutes obtained by tissue engineering techniques.

METHODS: Normal human skin biopsies were used to obtain primary cell cultures of human keratinocytes and fibroblasts. Once primary cell cultures were stablished, bioengineered skin tissues were generated using fibrin and agarose biomaterials and skin cells [3]. In this work, 4 experimental groups were analyzed: 1) acellular scaffolds; 2) dermal skin substitutes; 3) complete skin substitutes; 4) human native skin. All skin substitutes were kept in culture for 7, 14, 21 and 28 days. Biomechanical properties (Young’s modulus, break load, traction deformation, stress at fracture-break and strain at fracture break) were analyzed using an Instron mechanical testing analyzed. Results were analyzed using Kendall tau and Mann-Whitney statistical tests.

RESULTS & DISCUSSION: First, we found a significant correlation of the biomechanical properties of the different samples and the type of cells used, with the acellular samples showing the lowest values for all parameters. Complete skin substitutes with fibroblasts and keratinocytes did not differ from human control skin for traction deformation, stress at fracture-break and strain at fracture break) were analyzed using an Instron mechanical testing analyzed. No correlation was found between time in culture and biomechanical properties (p>0.05) for most study groups.

CONCLUSIONS: Our results suggest that the biomechanical properties of bioengineered skin substitutes directly depend on the type of cells used. In general, complete substitutes with fibroblasts and keratinocytes had the most appropriate biomechanical parameters as compared to native skin independently of the time of development in culture.

INTRODUCTION: Successful tissue or organ regeneration requires the induction of angiogenesis followed by the appropriate differentiation of progenitor cells to produce a functional repair tissue. The aim of this study was to 3D bioprint implants containing spatio-temporally defined patterns of growth factors to direct the regeneration of large femoral bone defects. These bioprinted constructs were designed to introduce a short-term (~10 days) gradient in vascular endothelial growth factor (VEGF) to enhance angiogenesis, followed by a delayed but sustained localization of bone morphogenic protein-2 (BMP-2) to regions of the femur where new bone formation is required.

METHODS: Bioinks were prepared by dissolving RGD functionalized, γ-irradiated alginate (3.5\%) and methylcellulose (1:2\%w/w) in αMEM, to generate the base bioink. To develop a vascular bioink that allows for controlled short-term release of VEGF, nano hydroxyapatite (nHA) (1:1\%w/w) was added. To develop an osteogenic bioink which slowly releases BMP-2 over time, laponite (6:1\%w/w) was added. Bioinks were printed within networks of PCL filaments to generate 3 experimental groups [1] VEGF Gradient – the vascular bioink loaded with 500ng/ml of VEGF in the centre of the implant and base bioink in the periphery; [2] BMP-2 gradient - the osteo bioink loaded with 8µg/mL BMP-2 in the implant periphery, with the base bioink in the centre; [3] Composite (VEGF+BMP-2) - the osteo bioink in the periphery with the vascular bioink in the centre. Constructs were either implanted subcutaneously into nude mice or into rat a 5mm segmental bone defect and compared to an empty defect. In vivo microct (\(\mu\)CT) was performed at 4, 8, 10 & 12 weeks. Repair was assessed histologically at weeks 2 & 12.

RESULTS & DISCUSSION: Printed gradients of VEGF were found to enhance angiogenesis of implants following subcutaneous implantation compared to implants homogenously patterned the same VEGF. 2 weeks after implantation into large bone defects, regeneration in all treatment groups was proceeding via an endochondral pathway. A significant increase in bone healing was only observed in the VEGF gradient group after 12 weeks, but occurred after 10 weeks in the BMP-2 gradient group, and as early as 8 weeks in the composite group. \(\mu\)CT reconstructions revealed that the composite group had the most consistent bone regeneration, with little ectopic bone formation. Bone preferentially formed in the annulus of the defect.

CONCLUSIONS: Using 3D bioprinting we were able to design constructs with spatio-temporal gradients in growth factors. The appropriate patterning of VEGF enhanced angiogenesis, and when coupled with defined BMP-2 localization, also enhanced bone healing with little ectopic bone formation. In conclusion, printing of distinct growth factor gradients allows for controlled tissue regeneration.

Identification of candidate adhesive proteins in Drosophila melanogaster saliva

INTRODUCTION: Drosophila salivary glands produce a proteinaceous glue that allows the animal to adhere to a substrate for several days during metamorphosis. Our aim is to use the powerful genetic tools of the model organism Drosophila melanogaster to explore the molecular basis for fly glue adhesion. We identified a set of proteins present in the glue and now plan to examine their role in adhesion.

METHODS: Available transcriptomic data [1] were analysed using bioinformatic tools in order to find proteins that are likely responsible for the glue adhesive properties [2] such as predicted peptide signal, amino acid enrichment bias, repeated sequences and basic isoelectric point. Preliminary tensile tests were performed with a universal testing machine (Ametek model LS1S/H/230V) on a pupa naturally attached to a glass slide and show that pupa adhesion is in the order of 10³ kPa. As the glue is water soluble, we also collected it by incubating pupae in water. We then placed the collected liquid on a glass slide covered by a cover slip and let it dry. We estimated adhesion by adding loads to the cover slip until detachment.

RESULTS & DISCUSSION: Among the 27 genes that have been identified as differentially expressed in the salivary glands and up-regulated before pupation [1], 25 code for proteins with predicted peptide signals. 12 of them present a high content of serine and threonine (more than 25% of the amino acids is serine or threonine), an isoelectric point superior than 8 except for one and repeated sequences, suggesting a potential role of these proteins in adhesion [2]. RNAi lines are available for all of these candidate genes except one in D. melanogaster. Candidate genes will be tested by crossing the corresponding available RNAi mutant lines with a Gal4 line that drives expression in the salivary gland. Adhesion tests are being developed to phenotype the mutants. Preliminary results show that adhesion for wild-type glue is in the order of 10² kPa for a protein concentration of 10² μg/ml.

CONCLUSIONS: Using transcriptomic data, we identified candidate genes that could be involved in pupa adhesion. These candidate genes will be analysed further for their impact on adhesion using an adhesion test specifically designed for our system.

INTRODUCTION: Digestive fistulas are disabling and challenging conditions urgently requiring innovative therapeutic approaches. We investigated herein the potential therapeutic benefit of a thermoresponsive Poloxamer 407 gel as a fistula occlusive and the combined action of extracellular vesicles (EVs) derived from porcine adipose tissue stromal cells (ADSCs), as cell-free regenerative effectors. We expect the thermoresponsive gel to be advantageous due the possibility of injection in its liquid form <20°C filling all the fistula tract, while gelling in situ at body temperature to facilitate retention, occlusive effect and sustained EV release. We explored, in a porcine fistula model, the healing potential of the combined product while the gel alone was also tested for one patient. Indeed, poloxamer 407 gel is authorized for clinical use as a vessel occlusive agent. Herein, we investigated, for the first time, its repurposing as a fistula occlusive agent.

METHODS: Esophageal fistulas were surgically created in pigs by placing two plastic stents during 30 days into their neck. Then, animals were randomized in 3 groups: control untreated one, a group treated with the gel at 20% alone (gel group), and a group treated with the gel at 20% containing 1.3 × 10^{11} EVs/ml (gel plus EVs group). Clinical, endoscopic and radiological evaluation of pig fistula healing was performed at day 30 and day 45, before histological assessment. A patient with colocutaneous fistula received an off-label treatment with a thermoresponsive Poloxamer 407 gel (20%). A total of 14 administrations during 7 weeks were performed. Fistula orifice size and secretion output were analyzed.

RESULTS & DISCUSSION: In the porcine study, complete fistula healing was reported to be 100% for the gel + EVs group, 67% for the gel group and 0% for the control. Only the combination of gel and EVs resulted in a statistically significant (i) reduction of fibrosis, (ii) decline of inflammatory response, (iii) decrease in the density of myofibroblasts and (iv) increase of angiogenesis. The gel treatment in one patient resulted in reduced fistula orifice diameter from 4.8 ± 0.5 to 1 mm and fistula output decreased from 425 ± 65 to 10 ± 4 mL, when comparing the months before and after therapy.

CONCLUSIONS: ADSC-EVs delivered into a thermosensitive gel induced total fistula healing in a pre-clinical swine fistula model. The gel itself was able to induce a therapeutic fistula occlusive effect in pigs and also in one patient, reducing fistula diameter and output. This study opens up new prospects for (i) local minimally-invasive EV delivery based on a thermo-actuated administration strategy in fistula therapy and (ii) the efficient repurposing of poloxamer 407 gel as a fistula occlusive agent [1].

INTRODUCTION: The skin is the outermost layer of the human and serves as the initial impermeable barrier that protects the human body from external harmful agents as well as restricting the loss of body fluids. Thus, the skin attracts much focus in the assessment of chemicals and pharmaceuticals. As an ethical alternative for skin toxicity testing, in-vitro-generated organ-like reconstructed human skin models have been developed by tissue engineering techniques. Although these models are applicable for many endpoints such as skin corrosion or skin irritation (OECD TG431/TG439), the only approved in vitro test methods are using epidermal models due to insufficient development of a permeability barrier of full-thickness skin equivalents [1]. The lacking barrier is caused by shrinkage of the skin equivalent [2]. The aim of this work was to improve the barrier function of a 3-layered in vitro skin model by adapting the culture conditions.

METHODS: The 3-layered skin model is comprised of primary human epidermal keratinocytes, primary human dermal fibroblasts and mature adipocytes. Cells were isolated from human skin and human subcutaneous adipose tissue. For 3D constructs fibroblasts and mature adipocytes were encapsulated in hydrogels based on collagen I. Both layers were casted underneath a transwell. Thereafter keratinocytes were seeded inside of a transwell for epidermal development. The improved model was compared to the standard setup. The epidermal shrinkage was measured over the culture time of 15 days. The barrier was quantified by an indirect barrier function test with triton X-100 and a permeability assay with sodium fluorescein and FITC-dextran. Furthermore, characterization of both models were conducted by immunofluorescence staining.

RESULTS & DISCUSSION: The improved setup led to a significant increase of the barrier function due to the prevented epidermal shrinkage. Primary human epidermal keratinocytes differentiated to a multi-layered epidermis with a well-formed basal layer and a dense stratum corneum. The differentiation was shown by immunofluorescence staining against cytokeratin 10 and 14, and filaggrin. Adipocyte specific proteins, perilipin A, laminin γ-1 and collagen IV (colIV) were verified by immunofluorescence staining.

CONCLUSIONS: The improvement auf the barrier of full-thickness skin equivalents is of great importance. Taken together, the results show that the modification of culture conditions lead to an improvement of the barrier function and to enhanced permeability properties without the loss of morphology features. The results show that the improved setup has great potential for meeting the challenges of alternative methods for animal testing.

Inflammation is still a problem in bone tissue transplantations due to the limitations of conventional antibiotic administration. Thus, traditional treatments have been replaced with local antibiotic therapies to overcome their limitations. Recently, there has been a significant increase on design of controlled drug releasing systems for the treatment of bone infections. Polymer based composite scaffolds have been used for controlled drug release at the defect area to treat the infection as well as regenerate the tissue. In this study, it is aimed to develop nanocomposite scaffold with functional POSS nanocage reinforcement (CS/POSS) and to immobilize the drug loaded chitosan/MMT composite nanospheres by coating the scaffold surface to provide controlled antibiotic delivery at the defect site. Gentamicin and vancomycin were selected as model antibiotic drugs and drug loaded chitosan/MMT nanospheres were fabricated with electrospray technique and characterized within the scope of morphology, hydrodynamic size, surface charge, FT-IR, in vitro drug release, antimicrobial activity and cytotoxicity. CS/POSS nanocomposites were fabricated via freeze-drying technique and characterized with mechanic, swelling test, SEM and micro CT analyses. Positively charged nanospheres with uniform morphology were obtained. High drug encapsulation efficiency (80-95%) and sustained release profile up to 25 days were achieved with a cumulative release of 80-90%. In addition, the release media of the nanospheres (6 h, 24 h and 25 days) showed a strong antimicrobial activity against S.aureus and E.coli, and did not show any cytotoxic effect to 3T3 and SaOS-2 cell lines. CS/POSS nanocomposites were obtained with high porosity (89%) and 223.3±55.2μm average pore size. POSS reinforcement increased the compression modulus from 755.7 to 846.1Pa for 10 % POSS addition. In vitro studies of nanosphere coated bilayer scaffolds were found cytocompatible with osteosarcoma and chondrosarcoma cell lines. Both of the cell lines successfully proliferated on chitosan/POSS scaffolds. ALP activity and osteocalcin secretion results showed that POSS nanoparticle incorporation significantly increased the osteogenic activity of Saos-2 cells. In addition, GAG and total collagen secretion were investigated with SW1353 cells cultured on scaffolds. In conclusion, these bilayer nanocomposite scaffolds can be considered as a potential candidate for infection preventive bone-cartilage interface with enhanced physico-chemical properties as well as biological activities.
Influence of the human cornea post-mortem time on human corneal epithelial cells used for tissue-engineered cornea

INTRODUCTION: Over the last decade, we developed a human tissue-engineered cornea (hTECs) that may serve as a model to study several biological processes, such as corneal wound healing. To produce a human cornea by tissue-engineering, self-renewal of the corneal epithelium through the maintenance of a sub-population of corneal stem cells is required in order to preserve its functionality. Human corneal epithelial cells (hCECs) that are isolated from human donor’s corneas should therefore be of a high quality. The goal of the present study was to determine whether long post-mortem times before cell isolation may impact on the hCECs’ proliferative capacity and wound healing properties using both monolayers of hCECs and hTECs as in vitro models.

METHODS: Ten populations of hCECs were isolated from human corneas at different times after donor’s death and separated in two groups: short (0, 1, 2, 3, 4 days after death) and long post-mortem times (15, 16, 17, 18, 19 days after death). Each population was grown as monolayers on several passages and the impact of the post-mortem time on hCECs’ proliferative potential analysed by colony-forming efficiency assays (P1 and P2) and growth rate measurements (P1 to P4). hTECs were produced by the self-assembly approach using hCECs from both post-mortem groups and wounded with a 8-mm biopsy punch. Wound healing was monitored until complete closure. Masson's trichrome staining (histological section) and indirect immunofluorescence against collagen IV, laminin V, fibronectin, ZO-1 and tenascin-C were performed to evaluate the impact of both short and long post-mortem times on the hTECs quality.

RESULTS & DISCUSSION: hCECs cultured from donor’s eyes with short post-mortem times have a higher growth rate and clonogenicity when compared to the long post-mortem time group as a result of a decreased doubling time at passages P1 to P4 and increased colony-forming efficiency with more holoclones at P1 and P2. However, no difference in the wound closure dynamic could be observed between hTECs prepared using hCECs with low and high post-mortem times. Furthermore, all hTECs had normal histological characteristics and stained positive for the extracellular matrix (ECM) components collagen IV and laminin V, as well as for the tight junction protein ZO-1. However, hTECs produced using low post-mortem time hCECs had a lower expression of the ECM components fibronectin and tenascin-C.

CONCLUSION: Our results suggest that there is a reverse relationship between post-mortem time and the proliferative capacity of hCECs. However, when used for the production of tissue-engineered corneas, these post-mortem, time-dependent proliferative variations of hCECs do not translate into any significant difference in the wound healing capacity of hTECs. Our study therefore provided evidence that donor’s eyes with long post-mortem times may be used as source of biological material for culturing hCECs that are to be used for the production of hTECs in vitro.
Controlled Delivery of hBMP-2 within a 3D Matrix Bioengineered with human-Mesenchymal Stem Cells: a FEM approach for growth factor mass transfer simulation

G. Della Porta, N. Maffulli
Presenting author: Giovanna Della Porta, gdellaporta@unisa.it

1Department of Medicine, Surgery and Dentistry, University of Salerno, Baronissi (SA), Italy

INTRODUCTION: Ordinate deposition of cells and biopolymer microcarriers for the controlled delivery of bioactive molecules within a 3D hydrogel can simulate an ordinate synthetic extracellular matrix [1-2]. In this work, human-Bone Morphogenetic Protein-2 (hBMP-2) release profiles from poly-lactic-co-glycolic acid (PLGA) microcarriers have been experimentally measured and a Finite Element Modelling approach was used for the prediction of hBMP-2 mass transport within a 3D scaffold bioengineered with Human-Mesenchymal Stem Cells (hMSCs).

METHODS: PLGA microspheres (800±100 nm) for the controlled release of hBMP-2 were fabricated by a proprietary technology (US Patent US/8628802 B2) and their release profile experimentally measured in DMEM at 37°C. hBMP-2 mass transfer was simulated into a 3D system using COMSOL Multiphysics®, taking into account its release profile and cell binding data [3]. hBMP-2 degradation rate was also taken into account in the simulations.

RESULTS & DISCUSSION: A simulation over a section of scaffold with volume of 3.4 mm³ was performed as snapshots of the whole geometry at 7, 14 and 21 days. The sensitivity analysis proposed allowed the identification of the optimum hBMP-2/PLGA microcarriers/hMSCs ratio within the 3D scaffold at to assure hBMP-2 concentration values within the range of 10-20 ng/cm³, as the minimum effective for hMSCs osteogenic stimulation. Moreover, hBMP-2 concentration profiles taken at different distances from the 3D scaffold center are superimposed and there is basically no radial profile within the considered system due to the very low alginate resistance to mass transfer Indeed, the calculated hBMP-2 diffusion coefficient (D) in Alginate was of 4-13 cm²/s; whereas, in PLGA was of 6-20 cm²/s.

CONCLUSIONS: The developed tool can be useful to predict the effective microenvironment formulation to assure effective bio-signal concentrations within the designed hydrogel microenvironment.

Quality of life in urogenital congenital malformations with existing lack of tissue
G. Reinfeldt Engberg1,2, M. Fossum1,2, A. Nordenskjöld1,2
Presenting Author: Gisela Reinfeldt Engberg, gisela.reinfeldt.engberg@ki.se
1Department of Women’s and Children’s Health and Center for Molecular Medicine, Karolinska
Institutet, Stockholm, Sweden 2Department of Highly Specialized Pediatric Surgery and Pediatric
Medicine, Astrid Lindgren Children’s Hospital, Karolinska University Hospital, Stockholm, Sweden

INTRODUCTION: Urogenital congenital malformations affect every ethnicity worldwide. These
malformations may manifest as lack of urinary bladder, vaginal, uterine, or penile urethral tissue, and
both environmental and genetic mechanisms are involved. Without reconstructive surgery these
malformations may have a high impact on quality of life, such as multiple infections, increased
demands of medical care and infertility. These factors may cause negative psycho-social effects with
impact on education, occupation and family building. Our research group has focused on analyzing
risk-factors and psycho-social effects of bladder extrophy, affecting 3:100 000 live born, in register-
based studies, as well as performing tissue engineering research within the field of reconstructive
urology [1-2].

METHODS: Matched cohort studies nested within the entire pool of live births in Sweden between
1952 and 2011 were conducted regarding bladder extrophy patients. Complete nationwide health,
birth and social registers were used, and cases were matched with 5 controls each. The objective was
to study proxies for quality of life such as maternal risk factors, birth descriptive data, comorbidity,
fertility, level of education, partnership and number of biological children.

RESULTS & DISCUSSION: Studies demonstrated no significant maternal risk factors and low
birth descriptive impact. Most children born with bladder extrophy had an isolated malformation.
Comorbidity, such as inguinal hernia and non-descended testis requiring surgery were more common.
Overall, educational and occupational levels were high and partnership formation was comparable to
controls. Fertility and the number of biological children was, however, significantly decreased [3].

CONCLUSIONS: The clinical aspect of infertility and fewer biological children demonstrate that
the surgical techniques in lack of tissue must be addressed in further research in basic science as well
as clinical and patient related studies. Introduction of better surgical techniques and progress in
application of regenerative medicine and tissue engineering contribute to higher quality of life for
patients with urogenital congenital malformations. There is, however, still a need for more advanced
applications of tissue engineering and tissue regeneration methods which would reduce the need for
use of autologous transplantation tissue from other organs. Targeted tissue engineering and
regenerative reconstruction techniques could minimize existing post-surgical comorbidity with
positive influence on quality of life. Further studies will address psychiatric impact on these patients
and the risk of developing urinary bladder cancer.

INTRODUCTION: Tooth loss remains a major health problem since current therapies are not able to regenerate damaged dental tissues including pulp and enamel. Successful pulp regeneration requires angiogenesis to supply nutrients and oxygen to newly formed tissue. Proangiogenic properties have already been assigned to dental pulp stem cells (DPSCs), mesenchymal stem cells (MSCs) residing in the dental pulp. For a long time, paracrine factors (e.g. VEGF) have been considered responsible angiogenic mediators. However, recent studies demonstrate that extracellular vesicles (EVs) derived from bone marrow-derived MSCs (BM-MSCs) also have the potential to enhance neovascularization. Therefore, our goal is to investigate the proangiogenic capacities of EVs produced by DPSCs in comparison with those of BM-MSC EVs.

METHODS: EVs were isolated from serum-free conditioned medium (CM) of DPSCs and BM-MSCs by differential ultracentrifugation. EV size and concentration were measured by Nanoparticle Tracking Analysis (NTA) and purity was confirmed by Western blot with enrichment of classical EV markers (CD9, CD63, CD81 and Annexin II) and absence of non-EV marker (mitochondrial Bax). The functional effect of EVs on the migration of human umbilical vein endothelial cells (HUVECs), as a key step in angiogenesis, was studied in a transwell system. The angiogenic profile of EVs was mapped by an antibody array. EV uptake by HUVECs was measured in time by fluorescence microscopy.

RESULTS & DISCUSSION: DPSC-derived EVs significantly induce HUVEC migration (n=8). However, this effect was less compared to BM-MSC EVs (n=6), which might be caused by the lower EV yield from DPSCs as measured by NTA. An antibody array revealed lower expression of proangiogenic factors (e.g. VEGF, MCP-1 and angiopoietin-1) and enrichment of antiangiogenic factors (e.g. TIMP-1) in EVs compared to EV-depleted CM of both cell types. A time-dependent EV uptake by HUVECs was observed.

CONCLUSIONS: Our preliminary data show promising in vitro proangiogenic effects of DPSC EVs. In the future, the potential of DPSC and BM-MSC EVs to induce blood vessel growth in ovo will be tested and ultrastructural analysis of both EV types will be performed. Acquired insights have positive implications for pulp tissue regeneration and diseases associated with insufficient angiogenesis, including stroke and myocardial infarction.

INTRODUCTION: Unlike heart valves, heart muscle has no replacement alternatives. The most challenging goal in the field of cardiac tissue engineering is to reestablish the structure and function of injured myocardium [1]. This study offers a newly tissue engineered hybrid cardiac patch that has promising mechanical properties for ventricular wall reconstruction.

METHODS: The left ventricular wall of fresh sheep hearts were dissected parallel to the epicardial plain into 3 mm-thick tissue slices. Myocardial slices were exposed to 1% sodium dodecyl sulfate (SDS) for 72 hours. Poly(glycerol-sebacate) (PGS) pre-polymer was synthesized via microwave irradiation and then, acellular myocardial tissue fragments embedded into the pre-polymer [2]. The cross-linking of PGS were performed in vacuum at 150 °C. To evaluate the cellular remnants and ECM components, native and decellularized myocardial tissues were stained with H&E, Masson's trichrome and DAPI. PicoGreen dsDNA quantification assay, hydroxyproline assay and DMMB test were applied to evaluate residual DNA, collagen and sGAG content. Structural characterization of cardiac patches was analyzed by FT-IR, DSC and NMR. Mechanical characterization was evaluated by tensile tests and SEM. Hybrid constructs were recellularized with Human Cardiomyocytes (Promocell, Germany). Cell viability and cytotoxicity analyses were also performed.

RESULTS & DISCUSSION: Following the 72-hour of decellularization process with 1% SDS, no residual cells were observed in H&E and DAPI staining. The DNA content was significantly reduced in the decellularized matrix compared to the native myocardium (96 ± 3.5 %). Analysis of the hybrid construct with SEM, FT-IR and DSC revealed significant alterations in compositional properties of the ECM. Mechanical properties of decellularized tissues were improved via in situ crosslinking of PGS elastomer.

CONCLUSIONS: We emphasis that PGS elastomers can be used to modify soft tissues to provide sufficient strength to decellularized matrices.

ACKNOWLEDGEMENTS: The authors would like to thank BMT Calsis Co for equipment support and TUBITAK for 2211-C Domestic Priority Areas PhD scholarship program and 1001 research grant (No:118M356).

INTRODUCTION: One of the major challenges in reconstruction of bone defects is the inadequate ability of designing biomimetic scaffolds that induces differentiation of osteoprogenitor cells by cell-matrix interaction at the nanoscale, as well as ensuring microvascular structure. Due to the inadequate mechanical properties, there are only few studies on building bone matrix mimetic scaffold by hydrogels. Therefore, there is still tremendous demand for new approaches and strategies for developing vascularized bone tissue. The objective of this study is to fabricate in vitro vascularized bone tissue model by using mesenchymal stem cell (MSC) laden nanofibers (NFs) reinforced hydrogels, which can support osteogenic and vasculogenic differentiation. In this study, NF reinforced vascularized bone tissue model was fabricated in vitro by using IKVAV and YIGSR peptide conjugated PEG-DA (Poly (ethylene glycol) diacrylate) hydrogel and EEGGC peptide conjugated NFs. Peptide conjugated NF and hydrogels that can induce osteogenesis and vasculogenesis will be developed and characterized.

METHODS: All peptide sequences were manually synthesized on 4-Methylbenzhydrylamine (MBHA) resin. After producing NFs with electrospinning, EEGGC and EEGGC peptides were conjugated to NFs with EDC/NHS chemistry. Next, 10% PEGDA was dissolved in 100 mM PBS and C-IKVAV and C-YIGSR peptides were added to this solution with a 1.1 molar ratio to conjugate with PEGDA. Human bone marrow MSCs (5x10\textsuperscript{4} cells/cm\textsuperscript{2}) were seeded on fibers and incubated for 1 hours at 37\textdegree C. After the hydrogel solution was filtered, HUVEC (10\textsuperscript{6} cells/mL) was encapsulated to solution. PEGDA solution was added to mold in 10mm diameter and crosslinked by UV. Layer by layer structure was produced with NFs and hydrogels. PEGDA solution and NF without peptide conjugation was used as negative control. MTT analysis of negative control group were evaluated at 1, 4, 7 days (d). Next, cell seeded fiber reinforced hydrogels incubated in osteogenic medium. Calcium Assay, ALP Assay and DNA quantification assay were evaluated on groups by 7d, 14d, 21d and 28d to compare the effect on calcium phosphate nucleation and osteogenic differentiation of MSCs.

RESULTS & DISCUSSION: Cell number was significantly increased after 7 days. Cell attachment and proliferation on fiber reinforced hydrogel model was successfully performed. Osteogenic differentiation studies are still in process and results will be presented in the conference.

CONCLUSIONS: Bone tissue model by using stem cell laden NF reinforced hydrogels was successfully fabricated in vitro. After osteogenic differentiation results are obtained, vasculogenic differentiation studies will be performed to develop vascularized bone tissue. This biomimetic approach to develop NF reinforced vascularized bone tissue model in vitro by using peptide conjugated hydrogel could be used for healing of metabolically demanding bone defects.

Co., Ltd, Seoul, Republic of Korea ³Predictive Model Research Center, Korea Institute of Toxicology, Daejeon, Republic of Korea

INTRODUCTION: Genetic polymorphisms, including single nucleotide polymorphisms (SNPs) in CYP genes lead to interindividual differences in hepatic metabolism, affecting on individual drug effects and toxicities. Here, we generated human induced pluripotent stem cell (hiPSC) lines having particular CYP genotypes (CYP2C19*2 / CYP3A5*3C) for the development of personalized drug therapy.

METHODS: 1,000,000 cells of LCLs were electroporated with 3 ug of each plasmid (pCXLE-hOCT3/4-shp53, pCXLE-hSK and pCXLE-hUL), which were used at 1600 V for 3 pulses of 10 ms each using Electroporator MP-100 (NanoEntek). Cell were seeded on matrigel-coated 6-well plates in mTeSR1 medium (STEMCELL Technologies) with 10uM Y-27632 (Merck Millipore) for 24 h and were changed every day with mTeSR. After 21-28 days of electroporation, iPSC-like colonies were appeared, then, each colony was transferred onto matrigel-coated plates and cultured.

RESULTS & DISCUSSION: Considering that LCL-derived iPSCs represented donor-specific traits [1], we generated iPSC from LCLs having a specific CYP polymorphisms in CYP2C19 or CYP3A5 or both, and wild type LCLs. We established LSCTR-LiPSC-6 (CYP2C19*2/CYP3A5*3C), LSCTR-LiPSC-2 (CYP3A5*3C), and LSCTR-LiPSC-3 (CYP2C19*2). They showed typical morphology of pluripotent stem cells, as seen in LSCTR-LiPSC-10 (Normal control). The expression of pluripotent stem cell markers (OCT4 and SSEA-4) and alkaline phosphatase (AP), together with three germ layer markers in the differentiated EBs were confirmed in these iPSC lines. All iPSC cell lines displayed normal karyotypes in the karyotyping analysis, and their SNPs in CYP genes were confirmed by comparing the SNPs with CYP-patient control, CYP-normal control, and negative control.

CONCLUSIONS: The established iPSC lines could be a valuable source for predicting individual drug responses and optimizing therapeutic drug doses for patients with defective CYP activities.

INTRODUCTION: Advances in material sciences have garnered interest in providing intrinsic material features; allowing stem cells commitment into desired phenotype [1]. Bone is a highly textured composite of submicrometric inorganic particles embedded in organic matrices. In vitro bone engineered tissue from stem cells differentiation was successfully achieved and reported. However, stem cells are a heterogeneous population with small proportion of osteoblast-committed cells, compromising thereby the use of standard molecular biology techniques to justify an effective differentiation [2]. Herein, imaging techniques are gathered in order to carry out bone engineered tissue analysis on micro/nanoscales

METHODS: Bio-inspired coating made of calcium phosphate/chitosan/hyaluronic acid was built up by simultaneous spray coating of interacting species [1]. Bone-like nodule (morphology/size) was followed by digital microscopy (Keyence, VHX-5000). Structural organization was investigated by histological stainings, field emission gun-scanning electron microscopy (FEG-SEM, JEOL JSM-7900F) and atomic force microscopy (AFM, Brucker). Chemical analysis were carried out on microscale using fourier transform infrared (IR) micro-spectroscopy (Brucker, Vertex 70v) and on nanoscale using an AFM-IR (Anasys, Nano-IR2).

RESULTS & DISCUSSION: After four weeks of culture on biomimetic material, human stem cells started to form nodules (≈ 0.4 mm² and 121 µm in area and height). Histological sections examination revealed cohesive tissue with continuous cell layers at the surface with randomly distributed cells embedded within newly formed collagen and proteoglycans. Infrared (IR) micro-spectroscopy at the scale of 40-80 µm in transmission and reflexion modes highlighted heterogeneities in the biochemical composition within the nodule as a function of the region. Major absorption features were attributed to amides bands from proteins, and characteristic bands from phospholipids, polysaccharides and phosphate bands from both organic and mineral origins. IR analysis performed by nanoIR at the scale of 50-100 nm confirmed heterogeneities in identified nodule cell-rich regions and in the organization of collagen fibril structures within nodule collagen-rich regions. Such heterogeneity is to be attributed to the relative contribution of ECM components (orientation, maturation…).

CONCLUSIONS: These findings shed the light of the potential application of spectroscopy as a tool for deciphering the chemical signature of in vitro generated bony tissues.

INTRODUCTION: Oceans, covering more than 70% of the earth surface, represent an enormous resource for natural products. Marine invertebrate molluscs, the largest animal phylum on earth, were tested for a broad range of biological activities. The extraction of bioactive agents of marine molluscs’ metabolites and/or shells is one of the most intensive areas of natural product research. Molluscs derived shells exhibit a remarkably stable organo-mineral biocomposite at the adult stage of the development. Among a large variety of molluscs, tropical Cowries (Mollusca; Gastro- poda; Cypraeidae) are used in many areas of medicine, including treatments of dyspepsia, jaundice, enlarged spleen and liver, asthma and cough. In light of these thoughts, we address, for the first time, the potential use of Cowrie's derived shell as a natural biomaterial for bone regeneration¹.

METHODS: Structural and chemical compositions were provided by scanning transmission electron microscopy (STEM), X-ray diffraction (XRD) and Fourier Transform Infrared Spectroscopy (FTIR). Cowrie's derived shell bioactivity was performed in culture medium using an induced coupled plasma-optical emission spectroscopy (ICP). Finally, Cowrie's derived shell cytocompatibility was investigated using mesenchymal stem cells (MSCs).

RESULTS & DISCUSSION: STEM micrograph of Cowrie's fracture showed “brick and mortar” structure with ordered lamellae of thin laths (around 300 nm of thickness). Composition, crystallographic and crystal chemical properties investigations revealed the presence of aragonite crystals. FTIR analysis showed that aragonite crystals were converted into poorly crystalline B- type carbonate apatite once soaked, at 37 °C, in DMEM culture media for 7 days, reflecting bioactive features. Cytotoxic assays showed that Cowrie's derived shell powder boosted human MSCs proliferation over the study time compared to nacre, used as positive control. MSCs adopted a flattened morphology and established physical contact with Cowrie's derived shell powder, signature of a good biocompatibility.

CONCLUSIONS: These results suggested that Cowrie's derived shell powder presents a great interest for bone regenerative medicine, and could be a useful and versatile carrier/scaffold for bone tissue engineering or a raw material for 3D printed orthopedic devices.

INTRODUCTION: Induced pluripotent stem cells (iPSCs) technology was discovered by Shinya Yamanaka’s lab in Kyoto, Japan [1]. iPSCs are able to differentiate towards cells from all three germ layers. Due to this capability, they can be used as a cell source for regenerative medicine applications and in vitro disease models. To date, culture substrates coated with Matrigel have been presenting promising results for iPSC culture and differentiation. On the one hand, Matrigel provides an improvement over standard monolayer cultures. On the other hand, it also raises difficulties such as batch-to-batch variation and complexity in composition [2]. To tackle these issues, engineered biomaterials can be fabricated by adjusting biological and biophysical characteristics to maintain iPSCs culture. Cellular behavior is controlled by a complex set of biophysical (e.g. stiffness, porosity, topography) as well as biochemical (e.g. matrix protein composition, growth factors) parameters. The aim of this study is to develop a fully synthetic iPSC-supporting gel that allows investigating the influence of biophysical, chemical and biological parameters on iPSCs.

METHODS: Heparin (Merk) and starPEG (JenKem) molecules with different molar ratios were successfully crosslinked to form biohybrid hydrogels. Stiffness of substrates was tuned by altering the molar ratios (1kPa-10kPa). Surfaces were then functionalized with 2 methods based on NHS ester binding to amine groups of laminins (method A and B). iPSCs were seeded on substrates in 24-well plates. The medium was changed every day (mTeSR, 10µM Rock inhibitor [Y-27632]). Cells were stained after 72 hours for pluripotency markers (OCT4-SSEA4).

RESULTS & DISCUSSION: No adherent cells were observed on the substrates with a storage modulus of 10kPa and 1kPa. iPSCs formed colonies after 24 hours on the substrates with 4kPa storage modulus. The ratio of different laminin types bound to the hydrogel surfaces also affected iPSCs' adhesion and colony formation. Laminin 521 and 111 functionalized hydrogels could mimic the matrigel as iPSCs maintained their pluripotency after 72 hours.

CONCLUSIONS: Laminin functionalized sPEG-heparin hydrogels clearly illustrated a suitable matrigel-mimetic growth substrate for the iPSC culture and maintainance of their pluripotency.

INTRODUCTION: Stem cells are frequently used in regenerative medicine [1]. They can be obtained from many resources such as bone marrow, adipose tissue, periosteum, etc. However, we used adipose tissue derived stem cells (ADSCs) in this study which is relatively easier to obtain and isolate [2]. This study is about comparing the mechanical isolation of ADSCs with a 3D printed Polylactic Acid (PLA) with or without coating. Herein, we used three coatings which are Hydroxyapatite (HAp), Aluminium Oxide (Al) and Zirconium Oxide (Zr).

METHODS: First of all, we prepared filtrates by using a custom-made 3D printer. 1.75 mm diameter thick PLA filament was extruded from a 300 μm nozzle by a speed of 60 mm/sec. Four filtrates with 2.5 mm thickness, 15 mm diameter and different pore sizes which are 530 μm, 365 μm, 310 μm, 165 μm were obtained. 3D printed PLA filtrates were grouped in four. First group was left without any coating. Other groups were coated with Hydroxyapatite(PLA-HAp), Aluminium Oxide (PLA-Al) and Zirconium Oxide (PLA-Zr) by using Sol-gel method. Characterizations were done by XRD and SEM. Also, we tried them with adipose tissue from a 81 years old woman patient. Flow cytometry analyses were performed with two markers of CD45 and CD34.

RESULTS & DISCUSSION: XRD and SEM results showed us that, we managed to coat PLA structures with the desired biomaterials. Moreover, flow cytometry results gave us ratio of cells with these markers below %5.

CONCLUSIONS: Flow cytometry analyses were performed for only two markers. They should be performed for more to make sure they are ADSCs. However, as being a pilot study, we aim to improve the coating techniques and perform additional in vitro analysis with more patients. Also, we might compare the results with enzymatic isolation of ADSCs. All in all, these filters give hope for a better mechanical ADSCs isolation technique.

INTRODUCTION: Calcium phosphate ceramics such as Hydroxyapatite (HAp), β-tricalcium phosphate (TCP) and Biphasic phosphate (BCP) have been widely investigated due to their intrinsic excellent biocompatibility as well as easy conducting of osteoblast cells. From our previous reports, hyaluronic acid-gelatin hydrogel (Hya-Gel) loaded BCP bone grafts showed active bone regeneration and angiogenesis, thus the defects which was using rabbit model were totally covered with new bones. In this work, we focused on the development of novel bone grafts which showing fast bone formation and hemostatic behavior. In particular, we will discuss the mechanical properties, hemostatic ability, in-vitro biocompatibility as well as bone regeneration capacity by the detailed in-vivo study using TCP loaded Hya-Gel/BCP bone grafts.

METHODS: BCP scaffolds were synthesized by combination of sponge replica, burning-out and sintering processes. As a core part, TCP powder loaded Hya-Gel was combined in BCP scaffolds. On these scaffolds, TCP powder loaded Hya-Gel was loaded again into the silicon molds and finally we could obtain the cone shaped TCP loaded Hya-Gel/BCP bone grafts. The microstructure and EDX analysis were visualized by scanning electron microscopy (SEM). To confirm the biocompatibility, we carried out MTT assay, immunostaining and hemo-compatibility. In addition, bone formation was identified by u-CT and histological analysis using rabbit femur defect model.

RESULTS & DISCUSSION: Outer and core zone of bone grafts showed highly porous morphology of Hya-Gel (A, B) and uniformed spread of TCP powder (C, D). BCP particle confirmed only in the core zone (E).

CONCLUSIONS: TCP loaded Hya-Gel/BCP bone grafts which has highly porous microstructure induced new bone formation by active osteoblast migration and promoted angiogenesis

Figure 1: Microstructure for core and outer zone of TCP loaded Hya-Gel/BCP bone grafts was evaluated by SEM (A, B); enlarged image (C–E).

INTRODUCTION: Flow focusing microfluidic devices have been investigated for the production of monodisperse populations of microbubbles for tissue engineering application. In this study, a newly designed microfluidic device based on flow-focusing geometry was developed to fabricate three-dimensional gelatin-poly (γ-glutamic acid) scaffolds of ordered pores for cartilage tissue engineering in the dynamic bioreactor cultivation.

METHODS: Scaffolds prepared by the flow-focusing microfluidic device. (Figure 1). 7% gelatin and 0.1% poly (γ-glutamic acid) prepared and crosslinked with EDC carbodiimide. The gelatin-poly (γ-glutamic acid) hydrogels were put into a syringe and dropped by the syringe pump. Nitrogen gas and gelatin-poly (γ-glutamic acid) hydrogels with 1% Pluronic® F127 surfactant were pumped through the inner and the outer channels, respectively. The scaffold was then put in the vacuum system overnight for removing air bubbles and synthesizing the interconnecting pore.

RESULTS & DISCUSSION: Scanning electron microscope and confocal microscope examinations showed that the microfluidic scaffold has a regular interconnected porous structure in the scale of 160 μm and high porosity (Figure 1, left). The scaffold is effective in chondrocyte culture; the live/dead cell viability (Figure 1, right), extracellular matrix production (glycosaminoglycans and collagen contents), cell proliferation (DNA contents), and gene expression (real-time PCR) all revealed good results in the dynamic bioreactor cultivation. The chondrocytes can maintain normal phenotypes, highly express aggrecan and type II collagen, and secrete a great deal of extracellular matrix.

CONCLUSIONS: Scaffolds prepared by a flow-focusing microfluidic device of highly ordered and uniform structures are desirable to control chondrocytes cellular behaviors.

Figure 1: (left) Uniform bubbles were generated and collected. (middle) SEM and (right) confocal microscopy showed the microbubbles self-assembled layer by layer. Chondrocytes were seeded in the microfluidic scaffolds and cultured for 1, 4, and 7 days in bioreactor cultivation.

ACKNOWLEDGEMENTS: Financial and microfluidic device supports were received from Ministry of Science and Technology (MOST) and Institute of Physics, Academic Sinica, Taiwan.
Bevacizumab inhibits choroid-retinal endothelial cells proliferation in three-dimensional modeling of angiogenesis

INTRODUCTION: Age-related macular degeneration and intraocular neovascular diseases have been treated clinically by anti-VEGF antibody drug bevacizumab. Previously, we have developed an intravitreal drug delivery system for bevacizumab sustained release using temperature-responsive hydrogels. In this study, we examined the anti-angiogenesis and apoptosis effects of bevacizumab on rhesus choroids-retina endothelial cells (RF/6A) in three-dimensional modeling of angiogenesis.

METHODS: Three-dimensional modeling of angiogenesis was using RF/6A cells encapsulated within photocurable hydrogels. Cell-laden poly (ethylene glycol) diacrylate (PEGDA) hydrogels were cultured in DMEM containing 10% FBS. The cell-laden constructs were treated with platelet rich plasma (PRP) and escalating doses of bevacizumab for 24 hours. The cells proliferation and cytotoxicity were assessed using LDH and live/dead viability assays. Morphological changes of vascular tubes formation on PEGDA hydrogels by endothelial cells were analyzed by bright field cell microscopy. Cell apoptosis in response to bevacizumab was measured by JC-1 staining.

RESULTS & DISCUSSION: Bevacizumab inhibited proliferation of choroids-retina endothelial cells in a dose-dependent fashion (Fig 1). The tube formation of RA/6A cells were significantly inhibited by bevacizumab in a dose-dependent manner (Fig 2). JC-1 staining showed that the % of apoptotic cells were also significantly increased in a dose-dependent treated cells (Fig 3).

CONCLUSIONS: Bevacizumab inhibits proliferation of choroids-retina endothelial cells and arresting the tube formation in a dose-dependent fashion in three-dimensional modeling of angiogenesis.

INTRODUCTION: Cartilage has a limited capacity to regenerate due to the avascular composition of the tissue and limited efficacy of current therapeutic interventions. Tissue engineering therapies rely on multiple concepts for scaffold design such surface chemistry, biocompatibility (decreased inflammation and immune response), mechanical properties, swelling, degradation profile, and porosity to integrate with the native host tissue. This paper investigates suitable photocurable hybrid hydrogels for cartilage replacements.

METHODS: Natural polymers (Alginate/Gelatin) were chemically-modified with methacrylate anhydride groups to induce photocurable macromers. Resulted bioinks were cured using ultraviolet light (UV) radiation (8 mW/cm²) for 8 min. hydrogel characrtization through ¹HNMR to confirm the functionalisation process was conducted. Morphological properties, swelling and degradation were assessed.

RESULTS & DISCUSSION: Mechanical compression test and rheological characterisation show that prepared bioinks present appropriate mechanical properties 35 kPa approximately, shear thinning behaviour and proper crosslinking structure to support or encapsulate cells during the Bio-printing process, allowing them to growth, proliferate and to produce their own extra cellular matrix (ECM). Furthermore, 3D cell culture shows that hybrid system has overcome some cell compatibility associated to lack of adhering side motifs of alginate with cells as the chondrocyte cell morphology were indicated more spherical shape in 3D compare to 2D.
Enhancing pancreatic islet-like cluster differentiation from hPSC by nanotopographical regulation using a gradient-pattern chip

Presenting Author: Hyojin Kim, 010hyojin@naver.com
1Laboratory of Stem Cells and Tissue Regeneration (LSCTR), Korea University, Seoul, Republic of Korea 2School of Biomedical Engineering, Korea University, Seoul, Republic of Korea 3Stem Cell and Regenerative Medicine Institute, Samsung Medical Center, Seoul, Republic of Korea 4Department of Legal Medicine, Korea University College of Medicine, Seoul, Republic of Korea 5Institute for Stem Cell and Regenerative Medicine, University of Washington, Seattle, USA

INTRODUCTION: In recent years, manipulating the micro- and nano-scale topography of the stem cell niche has gained considerable interest for the purposes of controlling extrinsic mechanical cues to regulate stem cell fate and behavior in vitro. Here, we established an optimal nanotopographical system to improve 3D differentiation of pancreatic cells from human pluripotent stem cells.

METHODS: H1 hESCs were differentiated into pancreatic islet-like cells under chemical and nanotopographical cues using some cytokines and gradient nano pattern chips with pillar of pore patterns.

RESULTS & DISCUSSION: Single sized nanopatterns have limited utility for testing wide ranges of topographical cues. So we established a gradient nanopattern system which are designed for a diverse range of patterns (pillar or pore) on a single chip. We induced H1 hESCs into pancreatic cells either on 3 different chips of gradient nanopillar patterns (Pi-1,2,3), 3 chips of gradient nanopore patterns (Po-1,2,3) or conventional flat surface dishes. The gradient Po-2 chips has the greatest potential to induce the formation of out-growing pancreatic bud-like structures which express pancreatic marker PDX1 and NGN3. Po-2 pattern-derived endocrine clusters could properly differentiated into functional islet-like 3D spheroids which contain insulin producing-cells and polyhormonal cells.

CONCLUSIONS: Collectively, we have developed gradient-nanopatterned chips to screen various surface nanostructures efficiently and identified that a Po-2 favors pancreatic islet cluster differentiation in the presence of soluble inducers.

INTRODUCTION: Cell replacement therapy using functional cardiomyocytes is a hot issue in cardiac regeneration. Direct lineage conversion of somatic cell into another functional cell type constitutes an attractive approach for research and clinical use [1]. However, until recently direct conversion has been accomplished by forcing expression of selected transcription factors using viral vectors [2]. Exosomes can mediate phenotypic changes by transferring functional signals and cellular reprogramming factors such as miRNAs between cells involved in various pathophysiological processes [3]. In this study, we present the first demonstration of efficient method for exosome-mediated direct conversion of fibroblasts into cardiomyocyte-like cells.

METHODS: To eliminate the effect of feeder layer cells and fetal bovine serum during the isolation of exosomes, we developed a serum and feeder-free two dimensional (2D)-directed differentiation system. Exosomes were isolated from the process of cardiomyocytes differentiation by using differential centrifugation. Exosomes and mouse embryonic fibroblasts (MEF) were co-cultured in defined media for 15 days for transdifferentiation. Induced cardiomyocytes (iCM) were characterized by immunocytochemistry, flow cytometry, quantitative real-time PCR, intra-cellular Ca2+ measurement, electrophysiological analysis, and Quantseq 3’ mRNA sequencing.

RESULTS & DISCUSSION: Cell clusters (day20) not only showed a positive response to the cardiac-specific markers: α-actinin, cardiac myosin heavy chain (α-MHC), cardiac troponin T (cTnT), and cardiac troponin I (cTnI), but also displayed clear sarcomere structures. Quantitative RT-PCR also confirmed that increase in the expression of cardiac-specific genes, including Tnnt2, Ryr2, Nkx2.5, and Gata4, compared with control MEF. The ventricular-specific marker, Mlc2v, was more expressed in iCM than Mlc2a, an atrial specific marker. Also, consistent with immuno-staining analysis, the action potentials (AP) were analyzed using the patch clamp technique, and many iCMs showed ventricular-like AP morphology with a mean diastolic potential (MDP) of -73.9 mV.

CONCLUSIONS: In summary, mouse fibroblasts could be converted to cardiomyocytes by a non-viral approach, and these exosome-mediated cardiomyocyte-like cells spontaneously contract, express cardiomyocyte-specific markers, and exhibit typical cardiac calcium flux and electrophysiological features. Our approach to exosome mediated cardiac reprogramming may be a simple and safe method to suggest a pathway that can be a step closer to clinical application.

INTRODUCTION: Hydrogels are three-dimensional network systems composed of polymer chains that exhibit a capacity to absorb and retain water from filling spaces between the chains. The crosslinking of some hydrogels occurs through thermosensitivity applied in the animal tissue, so it is possible to inject with minimally invasive techniques into their gel forms [1-2].

METHODS: 3 ml of injectable and thermosensitive hydrogel of Poly(NIPAAm-co-AAc-co-HEMA-PDLA-co-TMC) (12% m/v) with nankin ink and non-ionic iodinated contrast agent (Iopamiron®300) was implanted by needle on back subcutaneous tissue of 20 Wistar rats divided into 5 groups of 4 animals in periods of 1, 3, 5, 7 and 14 days. High Resolution Computed Tomography (HRCT) was performed on animals immediately after injection of hydrogel and after 24 hours. During all periods the tissue was surgically extracted and processed for histological analysis by Optical Microscopy and Confocal Laser Scanning Microscopy (CLSM).

RESULTS & DISCUSSION: HRCT performed after 24 hours of hydrogel injection and visualized subcutaneous cavities with release of water contained in polymer network, distributing in implanted area. Histological analysis by Optical Microscopy demonstrated formation of cavities on subcutaneous tissue and cellular migration to the implanted sites forming inflammatory-cicatricial lamina. Along periods these subcutaneous cavities were dividing in microcavities and mostly after 7 days was observed intense neovascularization surrounding microcavities, not detected apoptosis or necrosis. CLSM analysis was performed by indirect immunohistochemistry for α-SMA (alpha-smooth muscle actin) and observed at 5 days a structural reorganization of the regional vessels and after 14 days an extensive new capillary network in the areas adjacent the tissue where the hydrogel injection occurred. Myofibroblastic cells were not observed in any group.

CONCLUSIONS: Induction of the tissue reorganization after the hydrogel injection direct as a candidate for applications in tissue engineering, storing molecules and cells in microcavities and delivering through local neovascularization network. Cell delivery systems and molecules delivery systems, such as growth factors, cell differentiation factors, drugs or other modulatory molecule can be associated with the three-dimensional polymer network and could be applied promoting directed or local effects with long term delivery.

INTRODUCTION: One of the most promising approaches to cartilage tissue engineering is 3D bioprinting using cell spheroids generated from primary chondrocytes. However, obtaining the initial culture of these cells can be difficult. The present study examined spheroids formed by mesenchymal stromal cells (MSCs) of various origin for their suitability for cartilage bioprinting.

METHODS: MSCs were derived from human exfoliated deciduous tooth pulp, umbilical cord stroma and subcutaneous adipose tissue. Surface antigen expression was examined by flow cytometric analysis. Endotheliocytes were isolated from human umbilical cord veins (HUVECs, human umbilical vein endothelial cells). Chondrocytes were isolated from human costal cartilage. Spheroids were generated by aggregation of 8,000 cells in ultra-low attachment plates (Corning). Chondrogenic differentiation of cells comprising spheroids was induced by TGF-β1 (Peprotech). Histological analysis was carried out using staining with hematoxylin and eosin, Alcian blue staining for detection of glycosaminoglycans, and the Masson staining of collagen. Spheroid fusion assay was performed in ultra-low adhesion plates and monitored using the IncuCyte Zoom system (Essen Biosciences).

RESULTS & DISCUSSION: After confirming the presence of MSCs in obtained cultures, the cells were utilized for spheroid formation. The number of cells was chosen so that the diameter of resulting spheroids would be in the range of 200 – 300 μm, which was optimal for the FABION bioprinter (3D Bioprinting Solutions). After 14 days of chondrogenic induction, MSCs from all three sources showed significant signs of differentiation and progressively increased accumulation of cell-produced extracellular matrix containing collagen and glycosaminoglycans. In regard to in vitro chondrogenic potential, MSCs from adipose tissue were most similar to chondroblasts among all the MSC types tested. On the next step, multicellular spheroids combining MSCs and HUVECs were produced. The presence of endotheliocytes in the multicellular spheroids was confirmed by immunohistochemical staining with anti-CD-31 antibody (BD). The ability of spheroids obtained to fuse was successfully demonstrated, thus proving their applicability for bioprinting.

CONCLUSIONS: The data obtained suggest that MSCs from all the sources tested possess a pronounced chondrogenic potential when cultured in a form of spheroids. The ability of MSCs to form mixed MSC/HUVEC spheroids solves the problem of bioprinting of prevascularized tissue constructs. Thus, MSCs can be considered an accessible alternative to primary chondrocytes in the development of cartilage bioprinting techniques.

¹Department of Biomaterials, University of Bayreuth, Bayreuth, Germany

**INTRODUCTION:** Latest studies have shown great potential of polymeric self-folding films for cell patterning and tissue engineering [1]. Higher porosity ensures easier nutrient and byproduct exchange that can lead to better cell penetration. Until now, there is limited research on porous stimuli-responsive mats [2]. Additionally, porous electrospun mats improved the organization and maturation of engineered muscle tissue [3].

**METHODS:** Electrospun bilayer was prepared using polycaprolactone (PCL, passive layer) and methacrylated alginate (AA-MA, active layer). To obtain aligned PCL fibers we used two collectors: rotating drum and conductive parallel bars. PCL/AA-MA mat swelling was controlled using Ca²⁺ ion exchange. Mouse myoblast cells (C2C12) were cultured on double layer systems to investigate biocompatibility and formation of functional muscle tissue on fabricated scaffolds. Cell adhesion reagent was used to ensure good cell adhesion on PCL/AA-MA.

**RESULTS & DISCUSSION:** Evaluation of the cell viability at different time points showed the viability above 90% for all samples. The significant improvement in the cell alignment was seen for the cells, which were grown on bilayer after a week of culture. We recognized that cell growth and proliferation depends on each separate layer thickness. Muscle cells grown and differentiated on fibrous bilayer could be electrically stimulated showing the contraction of cells.

**CONCLUSIONS:** Fabricated bilayer system possesses positive effect on cell alignment and spreading, leading to more accessible biofabrication method for formation of highly structured tubular tissues like skeletal muscle fiber bundles.

INTRODUCTION: Several models of bioengineered human artificial corneas have been developed in the laboratory. One of the bioartificial corneas that have efficiently been used clinically is the fibrin-agarose bioartificial human cornea designed and developed by the Tissue Engineering Group of the University of Granada [1,2]. Although results are promising, novel extracorneal cell sources should be investigated. One possible alternative is the use of mesenchymal stem cells (MSC) [3]. The objective of this work is to describe a method to generate bioartificial human corneas using an alternative cell source and to analyze the main structural and histochemical features of these novel organs generated in the laboratory.

METHODS: Human bioartificial corneas were generated using nanostructured fibrin-agarose biomaterials with cornea keratocytes cultured within. For the generation of a cornea epithelium, umbilical cord mesenchymal stem cells (MSC) were isolated from Wharton’s jelly biopsies. Then, orthotypical corneas were generated by culturing cornea epithelial cells on top and heterotypical corneas were generated by using MSC as an epithelial substitute. Inductive differentiation media were used. Both corneas were grafted on the cornea of laboratory rabbits by anterior lamellar keratoplasty to determine their usefulness as anterior cornea replacements. Orthotypical and heterotypical bioartificial corneas were analyzed ex vivo and in vivo after 3 and 12 months of grafting.

RESULTS & DISCUSSION: Orthotypical and heterotypical bioartificial corneas were safely implanted in rabbit corneas and no mayor side effects were observed after 3 and 12 months. Clinical results as determined by slit lamp and OCT were positive after 12 months, especially in heterotypical corneas. Histology and immunohistochemistry demonstrated that both cornea types had moderate expression of stromal and epithelial cell markers ex vivo. Once grafted in vivo, corneas were highly differentiated, especially in the case of HHC.

CONCLUSIONS: These results suggest that orthotypical and heterotypical bioartificial cornea models could be potentially useful for the treatment of diseases requiring anterior cornea replacement and that heterotypical corneas could be efficiently used as an alternative to the use of orthotypical corneas without the need of generating cornea epithelial cell cultures.

INTRODUCTION: Several strategies have been successfully used to generate artificial oral mucosa substitutes (AOM). However, reconstruction of large oral mucosa defects is often challenging due to the limitations associated to the use of avascular constructs. For this reason, the aim of this study was to evaluate the capability of two mesenchymal stem cell types isolated from bone marrow (BMSC) and dental pulp (DPSC) to increase biocompatibility mediated by rapid blood vessels formation.

METHODS: AOM was developed based on FA hydrogels containing oral mucosa fibroblasts. To evaluate the vasculogenic potential of each cell type, the following study groups were established: 1) only fibroblasts, 2) fibroblasts and human endothelial cells (HUVEC), 3) native DPSC, 4) DPSC differentiated to the endothelial lineage using conditioning media, 5) native BMSC, 6) BMSC differentiated to the endothelial lineage using conditioning media. All these AOM models were grafted in vivo on nude athymic mice. Histological in vitro and in vivo analyses were performed by hematoxylin-eosin staining.

RESULTS & DISCUSSION: Macroscopical analysis showed the presence of a scar at the implant site in all experimental groups. Apart from this, the histological analysis revealed that all AOM kept in vitro showed spindle-like cells inside the stroma. In addition, at in vivo levels, two independent zones were detected between the construct and the host tissue: an interphase zone and a cell-rich zone. The interphase zone was mildly present in negative CTR and in group 4 with differentiated DPSC, being higher in group 6 (differentiated BMSC). The cell-rich zone tended to be moderate in groups 2 (HUVEC) and 3 (DPSC) and mildly present in 4 (differentiated DPSC). Moreover, vascular-like structures were found inside the stroma of the AOM, which were more abundant in group 3 (DPSC). Nevertheless, group 6 (differentiated BMSC) developed a low level of vascular-like structures while 2 (HUVEC), 5 (BMSC) and 4 (differentiated DPSC) showed a moderate vascular pattern.

CONCLUSIONS: These data suggest that the constant interphase zone in differentiated and nondifferentiated cells could be related with the intrinsic process of regeneration. Unpredictably, the vascular-like structures are independent of the process of differentiation. However, further experiments are required to determine the potential of MSC to induce neovascularization in AOM tissues.

ACKNOWLEDGEMENTS: Supported by the Spanish Plan Nacional de Investigación Científica, Desarrollo e Innovación Tecnológica (I+D+i) from the Spanish Ministry of Economy and Competitiveness (Instituto de Salud Carlos III), Grants FIS PI18/0331 and FIS PI18/0332 (cofinanced by FEDER funds, European Union).
Bioartificial gelatin coated PLGA membranes for wound healing
I. Carmagnola¹, A. Scalzone², P. Gentile², V. Chiono¹, G. Ciardelli¹,³

INTRODUCTION: Electrospun polymer mats have been widely used as scaffolds for soft tissue engineering due to the similarity to the extracellular matrix morphology [1, 2]. Bioartificial scaffolds based on synthetic and natural polymers lead to combine the processability and high mechanical properties of synthetic polymers with the bioactivity feature of natural materials. The aim of this work was to fabricate bioartificial electrospun membranes obtained through a strategy inspired by the mussel adhesion mechanism wound healing.

METHODS: Poly(lactic-co-glycolic) acid (lactide:glycolide 75:25, Mw: 66-107 kDa, Sigma-Aldrich, PLGA) was dissolved at 22% wt/v in acetone. Random fibres were produced at room temperature through an electrospinning equipment (Linari Engineering), setting at a flow rate of 1.5 mL/h, an applied voltage of 20 kV and a distance between collector and needle of 20 cm. 3,4-Dihydroxy-DL-phenylalanine (Sigma-Aldrich, DOPA) solution (2 mg/mL) was prepared using Tris/HCl 10 mM at pH 8.5 as buffered solution. After the dissolution of DOPA powder, PLGA membranes were dipping in a DOPA solution for 7 hours at room temperature under continuously stirring and in oxidative condition. Then PLGA fibres were washed and dipped in type A gelatin from porcine skin (Sigma-Aldrich, G) solution (2 mg/mL, Tris/HCl 10 mM, pH 8.5) for 16 hours. Samples were washed and dried at room temperature. Physico-chemical and biological analyses was performed in order to characterized the obtained bioartificial membranes.

RESULTS & DISCUSSION: Morphological analysis demonstrated that PLGA and functionalized PLGA fibres were randomly oriented and presented a porous network. After DOPA treatment the diameter average value increased significantly: 1.37 ± 0.52 µm and 2.94 ± 0.57 µm for PLGA and PLGA- DOPA respectively. The G grafting preserved the fibrous structured of the membranes, causing a further increase of fibre diameter. Infrared spectroscopy were used to highlight the successful addition of gelatin mediated by poly(DOPA) coating, where PLGA-DOPA spectrum showed the appearance of new peaks caused by the DOPA presence. After gelatin functionalization, ATR-FTIR spectrum clearly showed the characteristic peaks of the protein: the bands of the amide I, amide II, and the band attributable to the N-H and O-H stretching vibrations. Cell viability was performed by using Neonatal Normal Human Dermal Fibroblasts cells and gelatin coated membranes improved significantly cell adhesion.

CONCLUSIONS: A bioartificial and biomimetic system for soft tissue engineering was prepared through the immobilization of gelatin on dopamine modified PLGA membranes. PLGA membranes were used as substrates, while dopamine was employed as an intermediary to further graft gelatin. Electrospun matrices show morphological and compositional similarities to the natural ECM, with improved cell adhesion as demonstrated by cell response.

INTRODUCTION: Hydrogels have been considered as suitable materials for mineralized extracellular matrix analogue to be used for innovative tissue engineering therapies, but some lacks still concern their ability to mimic tissue microenvironment to promote cell differentiation into osteogenic way. In the last years, an increasing attention is growing towards micro-scaled hydrogels or μ-gels able to more efficiently support tissue regeneration by the delivery of bioactive signals, thus mimicking cell niche structure and functionalities. In this context, Electro Hydro Dynamic Atomization (EHDA) is emerging as a promising technique to encapsulate different bioactive species (i.e., drugs, proteins, mineral precursors). Herein, the use of composite μ-gels fabricated via EHDA is proposed to support the in vitro regeneration of mineralized tissues into dental cavities.

METHODS: Aqueous alginate solutions - from 0.5 to 2% wt/v -with and without mineral precursor were processed by EHDA. The solution was moved through a steel capillary – 0.2 or 0.8 mm as diameter – by different feed rates from 0.1 to 5 ml/h. A voltage (22kV) was applied to break polymer solution into micrometric droplets, then stabilized into the round shape after deposition in calcium chloride, CaCl₂, solution. a mineral precursor (Na₂HPO₄) was added to the polymer solution which was dripped into the calcium containing gelling bath to form mineralized stable μ-gels. These systems were characterized by optical and scanning electrical microscopy and FTIR. In vitro studies were also performed to validate their use as fillers to support the regeneration in dental cavities. Briefly, premolars teeth extracted for orthodontic reasons were cut transversely, washed and sterilized. Microspheres were placed in pulp cavity, and dental pulp cells were seeded.

RESULTS & DISCUSSION: Narrowly dispersed composite μ-gels with sizes ranging from 290 μm to 500 μm and round-like shape were fabricated by optimizing EHDA conditions. Characteristic peaks in FTIR and EDAX spectra confirmed the formation of calcium phosphates into the μ-gels. In vitro cell proliferation showed an increase rate until 14 days, opposite to the control (no microspheres). At 21 days, a decay of proliferation was recorded independently to the mineral amount, due to the starting differentiation state of cells. Accordingly, ALP activity related with osteogenic process increases after 14 and 21 days.

CONCLUSIONS: Composite μ-gels fabricated via EDHA contribute to generate a friendly microenvironment for cells able to recapitulate main activities involved in in vitro ECM mineralization, thus resulting a candidate material for hard dental tissues regeneration.

INTRODUCTION: Pigmentation is a result of the synthesis of melanin, which takes place in melanocytes, and its further distribution. Its dysregulation can result in loss of pigmentation, appearance of pigment spots, and melanoma. Development of new skin lightening drugs requires a simple and reproducible in vitro model. Tissue engineering is also a field that needs maintaining functional activity of different components. The aim of the study was to obtain and characterize spheroids from melanocytes and compare them to commercial skin equivalent.

METHODS: The study was conducted on primary culture of human melanocytes (CELL Applications) and skin equivalent Melanoderm (MatTek Corporation). Cells were cultured in monolayer up to the fourth passage in full growth medium (CELL Applications) and then transferred under non-adhesive conditions in agarose plates with microwells (Microtissue, USA). Melanoderm was cultured in specialized culture medium (MatTek Corporation). Spheroids and Melanoderm were cultured either in culture medium or in the presence of fucoxanthin (1:10) for one week and were then characterized using photometry, immunocytochemical staining, and real-time PCR.

RESULTS & DISCUSSION: Cells in primary culture synthesized melanin but its amount gradually reduced. When transferred in non-adhesive agarose plates, melanocytes aggregated and formed spheroids. Within the 7 days the amount of melanin elevated almost two times. Cells in spheroids expressed transcription factors that regulate melanogenesis: gp100, MITF и Sox10. Expression of both gp100 and MITF was up-regulated by day 3 and reached its maximum by day 7 in 3D culture. Real-time PCR revealed the expression of tyrosinase (TYR) – one of the melanogenesis enzyme, and MCR1 – the main receptor regulating melanin synthesis. Their expression was maintained during 3D culturing. Thus, spheroids provide maintenance of melanocytes’ functional activity comparable to that in multilayered skin equivalent Melanoderm.

Culturing both spheroids and Melanoderm for 7 days in the presence of the skin-lightening agent fucoxanthin resulted in the lower level of melanin, and in down-regulation of gp100, MITF, and TYR expression, thus inhibiting maturation of melanosomes and synthesis of melanin.

CONCLUSIONS: Collectively, these data illustrate that 3D culture system can better maintain the initial cell function in vitro compared to monolayer culture of melanocytes. The obtained spheroids can be used as a convenient and affordable test-system for drug screening and as building blocks for tissue engineering of skin equivalents.

ACKNOWLEDGEMENTS: This work was supported by the Research project “The study of mechanisms of aging and regeneration and development of conditions for obtaining tissue-engineered constructs using 2D and 3D cell cultures”.
Induced pluripotent stem cell-derived mesenchymal stem cells seeded on electrospun PCL nanofibers as matrix for tissue engineering

J. Seiler¹, K. Loger¹, L. Cyganek³, S.N. Gorb⁵, G. Lutter¹, I. Haben¹

Presenting Author: Irma Haben, irma.haben@uksh.de

INTRODUCTION: Induced pluripotent stem cells (iPSCs) have a high medical potential, which can be used to generate autologous mesenchymal stem cells (MSCs) for the individual patient. MSCs have the ability to differentiate into the various cell lines present in native valve leaflets and are therefore ideal candidates for vascular regenerative therapy. The choice of scaffold for cell seeding is crucial in cardiovascular tissue engineering, as it has to provide an appropriate basis for tissue growth and cell proliferation as well as biocompatibility, bioreabsorbability and excellent mechanical properties. Synthetic biodegradable polymers such as poly(ε-caprolactone) (PCL) combine these properties and 3D scaffolds can be designed by electrospinning. Here, we established and characterized the differentiation of iPSCs to iPSC-MSCs and compared the in vitro seeding capacity of iPSC-MSCs on electrospun PCL leaflets with differently oriented PCL nanofibers.

METHODS: The obtained human iPSCs were generated from the skin biopsy of a clinically silent healthy donor and kindly provided by the Stem Cell Unit, Heart Research Center Göttingen, Germany. iPSCs were cultured on a basement membrane-like matrix in special cell culture medium for stem cells. A two-phase protocol was established for differentiation of iPSC into iPSC-MSCs via the induction of mesoderm cells. Successful differentiation to mesoderm cells and iPSC-MSCs was performed by analysing Brachyury, Oct4 and Sox2 expression. Characterization of iPSC-MSCs was carried out by adherence to plastic, differentiation into bone, cartilage and fat cells, and analysis of surface expression. Cell lines tested positive in all assays were seeded on biodegradable, electrospun polymers with randomly oriented PCL nanofibers and aligned PCL nanofibers (Nanofiber Solutions, OH, USA). Analysis of surface colonization and surface topography quantified the seeding success.

RESULTS & DISCUSSION: Successful differentiation of iPSCs to mesoderm cells and iPSC-MSCs was confirmed by morphology and expression of pluripotency markers. The iPSC-MSCs were capable of differentiating into osteoblasts, adipocytes or chondrocytes and showed CD34⁻, CD44⁺, CD45⁻, CD90⁺, CD146⁺ and CD166⁺ surface expression. Seeding of iPSC-MSCs on electrospun PCL nanofibers resulted in a closed cell layer on the surface of the matrix. Topographic analysis indicated an enhanced adherence on randomly oriented PCL nanofibers.

CONCLUSIONS: We show that iPSC-MSCs can be easily generated by a skin biopsy of the patient. Randomly oriented PCL nanofibers seeded with iPSC-MSCs have a high potential to be used as a matrix for tissue engineering. Additional studies are needed to investigate the ingrowth of cells, formation of an extracellular matrix and the mechanical properties to quantify the functionality of the seeded matrices.
Shortened decellularization protocol for porcine pulmonary heart valves as matrix for seeding with human and ovine progenitor cells

M. Freytag¹, J. Seiler¹, A. Paur¹, S.N. Gorb², G. Lutter¹,³, I. Haben¹,³
Presenting author: Irma Haben, irma.haben@uksh.de

INTRODUCTION: Tissue engineering has the unique opportunity to provide a living valve, capable of growth and biological integration. Biological tissue has great potential to function as bioprostheses in patients for heart valve replacement. The challenge is to reduce immunogenicity without damaging the structure to allow recolonization with autologous cells. For clinical use, it is important that human cells adhere to the decellularized matrix. However, for our large animal model, decellularized heart valves need to be reseeded with ovine cells to generate autologous tissue engineered heart valves. Here, we established a new decellularization protocol for porcine pulmonary heart valves and reseeded the treated leaflets with human and ovine progenitor cells.

METHODS: Our new decellularization protocol is short in time (5 days) and includes a combination of NaOH, Triton X-100, Trypsin and endonucleases for the treatment of porcine pulmonary heart valves. Decellularization was assessed by histological and DNA analysis. Macroscopic structures and cytotoxicity of treated valves were analysed. Isolation of human EPCs from blood was confirmed by surface marker expression and formation of capillary-like structures. Isolation of ovine precursor cells was established and cell types were confirmed by surface marker expression. The decellularized leaflets were reseeded with human and ovine precursor cells with various seeding procedures. Histological and biochemical analysis quantified the reseeding success and morphology of the leaflets.

RESULTS & DISCUSSION: Histological analysis of decellularized leaflets revealed complete removal of all cellular components. The DNA amount was reduced by more than 98.4% compared to native porcine leaflets. The acellular heart valves showed an intact architecture, layer composition and surface topography. In addition, a cytotoxicity of the treated tissues was excluded. Reseeding of decellularized, porcine pulmonary valves with human EPCs resulted in a closed cell layer on the surface of the leaflet tissues. Similarly, decellularized leaflets reseeded with ovine progenitor cells showed cell attachment to the surface.

CONCLUSIONS: Our observations showed conserved leaflet structures after decellularization. Promising results in human and ovine cell reseeding indicated that the decellularized leaflets are suitable as an excellent scaffold for further application in tissue engineering. Additional studies are needed to investigate the mechanical properties to quantify the functionality of the reseeded leaflets before in vivo evaluation of the tissue engineered heart valves in the sheep model can be performed.

INTRODUCTION: Tendon-to-bone insertion exhibits a continuous structural and compositional gradient. Tendon-to-bone regeneration is limited due to disorganized matrix deposition occurring after injury. To overcome these challenges, we propose the assembly of microfibers with distinct topological and compositional features tailored to guide cell alignment and simultaneously match the mechanical properties of the native tissue.

METHODS: Textured composite microfibers were developed by wet spinning using two polymer blends, namely PCL/Gelatin (16/8, wt%) and PCL/Gelatin/Hydroxyapatite (HAp, 16/8/2.5, wt%). Fiber morphology and mechanical properties were evaluated. Mineral content was determined by alizarin red (AZ) staining and quantification. Human adipose stem cells (hASCs) were seeded to study cytoskeleton alignment and matrix mineralization. Textile techniques were used to create a 3D scaffold and the structure was analyzed by micro-CT.

RESULTS & DISCUSSION: Topographical and mechanical differences were observed between different extrusion flow rates. PCL/Gelatin fibers produced at 1 mL/h extrusion rate exhibited the highest anisotropic alignment, in opposition to PCL/Gelatin/HAp fibers under the same condition. Accordingly, seeded hASCs exhibited higher cytoskeleton alignment and nuclei elongation (p<0.0001) in PCL/Gelatin fibers. Significantly higher mineralization was found in PCL/Gelatin/HAp fibers (day 7, p < 0.04; day 14, p<0.0001) suggesting the induction of an osteogenic-like phenotype. As proof of concept, the two types of microfibers were assembled into a 3D scaffold with a gradual change in composition, resulting in a continuous gradient in HAp content, as well as topographical cues.

CONCLUSIONS: Continuous microfibers with distinct topological and compositional features were developed using a fast and simple wet spinning method. Aligned PCL/Gelatin fibers supported cell alignment replicating tendon cell organization, whereas PCL/Gelatin/HAp fibers triggered mineral deposition and possibly a phenotypic change. Fibers could be combined and assembled using straightforward textile techniques to create 3D scaffolds envisioning tendon-to-bone regeneration.

INTRODUCTION: Engineering tendon tissues requires a multi-component, multi-scale strategy. Composite living fibers (CLF) have been developed comprising a mechanically competent core and a cell-laden hydrogel shell [1,2]. Herein, we explored different hydrogel coatings and cell sources to generate artificial living tendon grafts.

METHODS: Commercial sutures were coated using two different strategies. First, an alginate and methacryloyl gelatin (Alg:GelMA) hydrogel was produced by ionic gelation in a CaCl2 bath and subsequent photocrosslinking by UV light. Here, tendon derived cells (TDCs) were encapsulated. Alternatively, bio-functionality was introduced by developing a platelet lysate (PL) hydrogel through thrombin/CaCl2 crosslinking and adipose stem cells (ASCs) were encapsulated. Cell viability (live/dead and alamar blue assays), alignment and expression of tenogenic markers were assessed. Textile techniques were used to generate a 3D construct.

RESULTS & DISCUSSION: The hydrogel layer provided a hydrated microenvironment adequate for cell encapsulation. Both TDCs and ASCs were viable and metabolically active immediately after the coating processes and up to 21 days in culture. In Alg:GelMA hydrogel, TDCs were able to migrate from the outer layer to the surface of the core fiber. In PL hydrogel, the incorporation of this cocktail of biomolecules allowed a fast contraction of the hydrogel by encapsulated ASCs, accelerating the process of migration and microenvironment remodeling by cells. Both cell types were able to align following the direction of the fiber and resembling tendon anisotropic organization. Collagen type I (COL1) expression was assessed (Fig. 1). In both strategies, COL1 could be detected. Strikingly, ASCs in PL hydrogel extensively deposited COL1 in an aligned manner. Due to the demanding mechanical requirements of tendon tissue, the core suture provides a robust mechanical support, which was further improved in textile assembled structures, to sustain tissue level needs.

CONCLUSIONS: As multi-compartment fibers, CLF enable the simultaneous recreation of tissue- and cellular level properties, emulating tendon organization.

INTRODUCTION: Nasal defects that affect tissues such as cartilage or bone can be irreversible and become a challenge not only for the laryngologist but also for plastic surgeons. Even small osteochondral defects may necessitate surgical intervention. Nowadays tissue engineering has appeared as a new approach in treatment of damaged or lost bone and cartilage. In this work, an attempt at combining the advantages of 3D printing and electrospinning was carried out in order to produce scaffolds for TE. It was hypothesized that a composition scaffold combining 3D printed composite porous structure together with nanofibrous nonwovens (containing bioactive and antibacterial additives) can satisfy the biological requirements of scaffolds and provide nasal structural support.

METHODS: Scaffolds were successfully printed using laboratory-made polymeric sticks (modified with bioactive and antibacterial additives) fabricated by injection moulding method. Poly(ɛ-caprolactone) (PCL) (molecular weight: 80 kDA) and graphene nanoplatelets (powder) were purchase from Sigma Aldrich. Bioactive glass (BG) A2 of the following composition (mol%) 40SiO2–54CaO–6P2O5 was produced at UST-AGH (Kraków, Poland) using the sol–gel method. Osteogenon (Osteo, PIERRE FABRE) is an ossein-hydroxyapatite complex (OHC) also containing osteocalcin and type I collagen. Osteogenon (Osteo) was used as bioactive powder and added to the electrospinning solutions. The composite filament sticks (PCL/graphene; PCL/BG) were used for 3D printing (Fused Deposition Modelling (FDM) technique). In order to prepare fibrous PCL/Osteo or PCL/BG layer on the top of 3D printed scaffold, electrospinning setup (TIC 1092012) was applied. Primary Human Chondrocytes (HCH), Murine fibroblasts L929 (ATCC, USA) and Normal Human Osteoblasts (NHOst, Lonza, USA) were cultured on prepared materials. In order to determine proliferation rate of cells and cytotoxic effect of obtained materials, ToxiLight™ BioAssay Kit and ToxiLight™ 100% Lysis Reagent Set (Lonza, USA) were used according to manufacturer’s protocol. Mineralization was assessed by OsteoImage mineralization test (Lonza, USA).

CONCLUSIONS: We expect that the resulting scaffold will have the potential to mimic both the cartilage and subchondral bone tissues needed for nasal defects treatment.

ACKNOWLEDGEMENTS: Financial support was received from the National Science Centre, Poland in the frame of Sonata Bis 5 project: “Layered scaffolds for nasal cartilages reconstruction fabricated by 3D printing and electrospinning” 2015/18/E/ST5/00189.

INTRODUCTION: Most tissues in human body including muscles, tendons, and nerves show aligned microfibril structures [1]. Especially, skeletal muscle tissue is composed of uniaxially oriented myotubes. For this reason, biomimicking the structure can be a strategy for muscle tissue regeneration [1]. However, the fabrication of aligned microstructures with homogeneously distributed and aligned myoblasts has been remained as the main assignment. In this study, we used melt-electrohydrodynamic (MEHD) to provide topological cues for better cell alignment. We achieved highly aligned PCL/gelatin multilayer structure and the cells were highly aligned after several days of culture.

METHODS: This process uses a melt-electrohydrodynamic (MEHD) process to fabricate PCL bundle with aligned micro fibrous structure. After printing of gelatin (MP bio, Korea) scaffold, melt-electrohydrodynamic was conducted using gelatin as an electrode. As the PCL bundles were stacked on top of the gelatin scaffold by the electric field, the PCL/Gelatin multilayered scaffold is fabricated. Normal printing of PCL on the gelatin structure was used as control group. C2C12 cells were seeded and cultured on the multilayered scaffold in Dulbecco’s modified Eagle’s medium (DMEM). The effects of aligned microfibrous structure on cells were determined using DAPI/phalloidin staining after 7 days.

RESULTS & DISCUSSION: We could decrease the diameter of scaffold from 250 µm (nozzle diameter) to 20 µm by adjusting the process parameters. Two groups of multilayer scaffolds (MEHD and normal printing) were examined using DAPI/phalloidin staining. The cytoskeleton and nuclei of cells in aligned scaffold were shown highly aligned to the direction of the aligned microfibrils compared to the control. The micro aligned structure can induce cell orientation and myogenic differentiation more efficiently than normally printed flat PCL/gelatin multilayer scaffold.

CONCLUSIONS: In this study, we developed an innovative printing technique for in situ cell alignment using MEHD. PCL/gelatin multilayer scaffold with MEHD presented a significantly oriented cytoskeleton compared to control. Based on the results, we concluded that the fabrication process of the PCL/gelatin multilayer structure with MEHD can be a promising method for various tissue regeneration.

INTRODUCTION: Extracellular matrix (ECM) stiffness, one of the principal biomechanical cues of the cellular micro-environment, is known to be critical in regulating cell behavior as well as in directing the development of tissue fibrosis [1, 2]. The examination of very localized micromechanical data on cells and its surrounding ECM is challenging due to the structural nature of cells and ECM-like materials [3]. We therefore present a new instrumental method of superimposing micromechanical and imaging data of Fibroblasts inside a collagen-based scaffold by integrated nanoindentation microscopy and incubation.

METHODS: For both the micro-mechanical testing as well as the microscopical analysis a newly developed instrument, the Pavone, is used. The Pavone introduces the semi-automated integration of micro-mechanical and microscopical data, allowing to resolve structure-function relationships of cells and their surroundings. Micromechanical data was collected through nanoindentation experiments, performed in culture medium. The mechanical testing capabilities range from quasi-static experiments to derive elastic moduli, to step-response tests (e.g. creep, stress-relaxation), dynamic mechanical analysis (micro-DMA) and constant strain rate tests to characterize sample viscoelastic behavior, as showed on the cell-matrix construct in this study. For microscopic analysis, the modular inverted microscope, built-in the Pavone, is employed and correlated with the micromechanical dataset. To demonstrate these novel analysis capabilities on cell-ECM-like constructs fibroblast where cultured for 4 weeks in an ECM-like collagen gel inside a 96 well-plate.

RESULTS & DISCUSSION: For Fibroblast-collagen constructs, this technique can accurately determine moduli in the range between hundreds of Pa up to a few kPa to investigate regional differences in stiffness of cell and non-cell containing regions of the collagen gel.

CONCLUSIONS: The collected preliminary data on Fibroblast-seeded collagen gels demonstrate the ability of the featured automated nanoindentation setup to investigate large quantities of indentation points in short time. This allows, with high spatial and temporal resolution, to obtain insights in structural properties of living bio-samples, along with micromechanical characterization, in a non-destructive way.

ACKNOWLEDGEMENTS: Financial support as well as the Piuma Nanoindenter setup was received and sponsored by Optics11, Amsterdam, NL.

A growing number of patients suffering from obesity and type 2 diabetes, both civilization diseases, combined with other risk factors, means also a growing number of patients suffering from cartilage lesions. The development of osteoarthritis (OA), a degenerative and inflammatory joint disease, has an effect on the cartilage, subchondral bone and joint tissues. With this in mind, there is no surprise that its treatment is complex and at the same time may be hindered by properties of the damaged tissue itself, like lack of vasculature in case of cartilage. Moreover, the chosen therapy should consider different requirements of the gradient structures formed by the cartilage and subchondral bone. Scientists are still in search for an optimal solution within tissue engineering and regenerative medicine fields that will not only give some level of pain relief but also, or in the first place, will prevent further damage and allow regeneration of defected areas. Our research is focused on the development of various types of scaffolds based on polysaccharides (eg. chitosan and sodium hyaluronate) that are combined with hydroxyapatite and graphene family materials (GFM) to form gradient structures. In search for an ideal material solution, we have tested different forms of those, such as injectable hydrogels, porous scaffolds, microparticles that can additionally serve as bioactive molecules delivery agents, etc. Recently, we have obtained hierarchical chitosan/graphene oxide scaffolds modified with electrospun polylactide/hydroxyapatite nanofibers. The detailed physicochemical characterization that consists of structural, microstructural, mechanical, rheological, thermal, chemical stability and surface analysis tests has a crucial importance when such a large variety of materials is considered. We aimed to choose only the most promising ones for further, biological tests. Following biomimetic approach, we are trying to develop materials close to native tissues that will best serve as part of the biomaterials-assisted cell therapy of osteoarthritis. Ideally, they should guide and stimulate differentiation of mesenchymal stem cells and constitute appropriate support for successful tissue formation. This is initially tested in the in vitro conditions. However, one has to remember that only in vivo studies can verify all assumptions and materials choices.

ACKNOWLEDGEMENTS: The authors would like to thank the National Centre for Research and Development, Poland for providing financial support to this project (STRATEGMED3/303570/7/NCBR/2017).
INTRODUCTION: Corneal damage is one of the most common causes of impaired vision or even blindness. When the injury is more extensive and the limbal region is involved, the regeneration of cornea is not sufficient. Such damage can lead to limbal stem cell deficiency (LSCD). Nowadays the only option for LSCD treatment is transplantation of the limbal tissue or a transfer of limbal stem cells (LSCs) cultured from the healthy eye. In the case of bilateral LSCD the only option is allogeneic transplantation of the limbus or cultured LSCs with systemic administration of immunosuppressive drugs. As an alternative, mesenchymal stem cells (MSCs) turned out to be a suitable source of autologous stem cells. Despite the large number of experimental works on stem cell therapy of LSCD [1-3], the mechanism of MSC inhibitory properties on the ocular surface is still not well recognized.

METHODS: MSCs were obtained from the murine bone marrow. Flow cytometry was used to characterize the phenotypic markers of such MSCs. For in vitro experiments MSCs were cultured in 48-well plates for 24 hours. Excised corneas were added to cultures alone or in inserts and stimulated by proinflammatory cytokines. After a 48-hour co-cultivation the expression of genes for inflammation cytokines and other molecules in the corneas was detected using qPCR. To elucidate cytokine production by MSCs co-cultured with corneas, inserts were used in to separate MSCs and corneas. In in vivo experiments, MSCs were seeded onto nanofiber scaffolds (allowed to adhere for 24 hours) and transplanted on the injured (0.25M NaOH, 20 seconds) cornea.

RESULTS & DISCUSSION: Expression of genes for IL-1, IL-6, iNOS and VEGF expression was reduced after the treatment of damaged corneas with MSCs in in vivo experiments. Transparency of corneas treated with MSCs was better than in untreated injured controls or nanofiber scaffold control. In in vitro experiments the expression of IL-1, iNOS, TNF-α and VEGF was reduced in corneas cultured directly with MSCs. IL-6 expression was decreased in corneas cultured in inserts or with MSC supernatant alone.

CONCLUSIONS: Autologous MSCs seeded on nanofiber scaffold represent a suitable source of stem cells for the therapy of LSCD, when there is no possibility to use LSCs. MSCs inhibit a local production of proinflammatory cytokines and help to regenerate the corneal epithelium. Our in vitro model would help us to explore in more details the therapeutic effects of transplanted MSCs.

INTRODUCTION: Allogenic human pericardium and xenogeneic pericardium are used as biomaterials for applications in cardiovascular surgery. [1]. The pericardia have to be processed prior implantation in order to reduce immunological response of the recipient’s organism. The immunogenicity of the pericardia can be also decreased by decellularizing pericardial tissue which results in cell-free scaffold composed of generally less immunogenic extracellular matrix proteins. Even after the removal of cellular content, the tissue is often treated with glutaraldehyde (GA). The crosslinking blocks immunogenic cellular residues remaining in some cases in the decellularized tissue, improves its mechanical properties, and increases the graft durability by reducing its biodegradability. However, GA-treated tissues are prone to calcification after long-term implantation [1, 2]

METHODS: In this study, the pericardium was decellularized, crosslinked with GA or genipin and subsequently coated with pure fibrin meshes and meshes modified by the attachment of heparin and/or fibronectin. We focused on testing of mechanical properties, possible toxicity of the crosslinking agent and on the improvement of the endothelial cell growth. Effects of the crosslinking on mechanical properties and collagen structure of the decellularized pericardium were estimated by uniaxial tensile test and multiphoton microscopy, respectively. Viability and metabolic activity of human umbilical vein endothelial cells (HUVEC), seeded on these samples, were then evaluated by a MTS assay in order to find a potential way by which in situ endothelialization of non-autologous pericardium grafts could be encouraged.

RESULTS & DISCUSSION: Viability of the cells measured by their metabolic activity decreased considerably if pericardium was crosslinked with glutaraldehyde. On the other hand the cell viability even increased if pericardium was crosslinked with genipin. The coating of both unmodified and crosslinked pericardium with a fibrin mesh or with the mesh containing attached heparin and/or fibronectin increased significantly the cell viability.

INTRODUCTION: The fibers or non-woven textiles made of native hyaluronic acid (HA) are highly soluble materials with no direct application in tissue engineering or regenerative medicine. By its conjugation with short peptides, we are able to stabilize the structure and furthermore add a functionality to the material using antimicrobial peptide, healing peptide or adhesive peptides supporting cellular adhesion [1].

METHODS: HA (Mw 1 MDa, Contipro a. s., Czech Republic) fibers were prepared by wet spinning technology. Cutting fibers by mixer with subsequent compressed filtration create form of non-woven textile. The material was used as a carrier for peptide synthesis using Fmoc/tertBu protection. Peptides supporting cellular adhesion (RGD, IKVAV etc.) were used to confirm the functionality of this conjugate. Dermal fibroblasts (NHDF) and adipose stem cells predifferentiated to cardiomyocytes (ADSC) were stained by DiI, seeded on this material and their adhesion and proliferation was monitored under the fluorescent microscope (Nikon Eclipse-Ti) within 7 days of cultivation. The detail of adhesion as actin filaments and vinculin visualization was captured under the confocal microscope (Leica TCS SP8 X).

RESULTS & DISCUSSION: Double 6-aminohexanoic acid spacer (Ahx) was used with advantage compared to triple glycine, to connect the peptide with HA and made it accessible for cellular binding proteins. The non-woven textile was stable under the cultivation conditions for more than 7 days. The different concentrations of RGD-Ahx peptide was analyzed for NHDF adhesion. The higher the concentration of RGD, the more NHDF adhered. Contrary, using DGR-Ahx peptide was without the effect, as well as adhesion on the Ahx linker alone. ADSC adhered uniformly on GGEGYGEGYIGSR-Ahx-O-HA non-woven textile as YIGSR should support the adhesion of cardiac myocytes [2]. Oppositely, they attached poorly on IKVAV-Ahx peptide, which is primarily used for adhesion of neurons [3].

CONCLUSIONS: The peptide-HA complex is water insoluble, but enzymatically degradable and biocompatible. We are able to control its synthesis by the addition of different peptide equivalents. These peptides are accessible for cellular integrins enabling focal adhesion and their activity is maintained. Furthermore, the prolonged stability (more than 7 days) predetermine applicability of this functionalized non-woven textile in tissue engineering and regenerative medicine.

INTRODUCTION: Skeletal muscle tissue engineering (SMTE) presents a promising strategy for generating platforms to study muscle development and diseases [1,2]. Herein, we aimed at identifying the effects of various types of physiological and non-physiological mechanical stimulation on the myogenic outcome of a SMTE approach.

METHODS: Murine myoblasts (C2C12) were embedded in ring-shaped fibrin hydrogels and subjected to mechanical stimulation in a custom-made bioreactor system (MagneTissue) [2]. Varying training protocols exerting physiological strain (10% tensile stress, static or cyclic with 0.25 Hz) were applied continuously or with resting phases during early myogenesis. Furthermore, pre-differentiated constructs were exposed to injurious loads of static and cyclic strain (40% static stress, or 10% cyclic stress with 1.2 Hz).

RESULTS & DISCUSSION: Gene expression analysis of early, mid and late-stage myogenic markers (MyoD, myoG, myosin heavy chain (MHC) and troponin T 1) and immunofluorescence stainings for MHC showed that cyclic mechanical stimulation promoted late-stage myogenesis to a higher extent than static stimulation, whereas an opposite trend was observed for early myogenesis (data not shown). Furthermore, it was demonstrated that application of strain with shorter resting phases significantly increased MHC 2b synthesis, an isoform expressed in the last stages of differentiation in C2C12 [3]. Simulation of injuries to mature SMTE constructs revealed that high frequency cyclic stimulation (1.2 Hz) resulted in randomly oriented myotubes with a hypertrophic phenotype, while static tensile stress (40% of initial length) yielded highly-aligned, thicker myotubes.

CONCLUSIONS: It can be concluded that type (cyclic vs. static), and time point of mechanical stimulation, as well as duration of resting phases have a major impact on progress of myogenesis, MHC isoform transition and morphology of myotubes.

Functional correction of hemophilia A phenotype using patient-derived iPSCs and genome editing
J.S. Son, J.H Kim
Presenting Author: Jeongsang Son, sllzzz@naver.com
Laboratory of Stem Cell Biology, Division of Biotechnology, College of Life Science & Biotechnology, Korea University, Seoul 126-713, Korea

INTRODUCTION: Hemophilia A (HA) is a recessive X-chromosome linked bleeding disorder, in which factor VIII (FVIII) is insufficiently synthesized or does not properly function [1]. The current study was carried out to investigate the therapeutic potential of highly purified endothelial cells (ECs) derived from HA patient-IPS cells carrying FVIII corrected by CRISPR/cas9.

METHODS: The original HA patient-derived iPSCs (iPA) and FVIII gene-corrected iPSCs (iCO) were both differentiated into ECs through purification and proliferation steps. The iPSC-derived ECs (ECs from iPA and iCO) were transplanted into HA mouse after two passages. To evaluate the therapeutic ability of grafted iPSC-ECs, total bleeding time after tail vein transection (TVTB) [2] and mice survival rates after tail clipping was measured and compared between the cell types and doses after 2 weeks of transplantation.

RESULTS & DISCUSSION: qPCR and immunostaining data showed that iPSC-ECs expressed multiple EC markers, including CD31, vWF and VE-cadherin. They were capable of Ac-LDL uptake and formed tube-like structures on solidified Matrigel. The level of FVIII coagulant antigen (FVIII:Ag) was ~ 5 ng in lysate of 1 x 10^6 iCO-ECs, which corresponds to one-third of that of human liver sinusoid ECs, known to be the main cell type that produces FVIII. After transplantation into HA mice, TVTB data demonstrated that the average of total bleeding time significantly decreased (Sham: 38m 38s, iPA-EC: 41m 53s, iCO-EC: 11m 25s). Tail clipping survival test showed that phenotypic correction was acquired through iCO-EC transplantation: 20% of animal survived after transplantation of 2 x 10^6 cells and 90% survived after 4 x 10^6 cell grafting. Furthermore, FVIII activity in blood plasma of HA mice was increased and reached up to 15% of the normal level.

CONCLUSIONS: HA patient-derived iPSCs could differentiate into ECs that produce functional FVIII after CRISPR/Cas9-mediated gene correction. The genome-corrected HA-iPSC can be used in cell therapy for the treatment of HA.

ACKNOWLEDGEMENTS: We thank Dr. J. S. Kim and Dr. D. W. Kim for providing iPSC lines.

INTRODUCTION: Hepatocytes and hepatic progenitors derived from human pluripotent stem cells (hPSCs) are useful sources for both therapeutic and pharmaceutical application. Therefore, identification and purification of these cell types would be important issues after hepatic differentiation of hPSCs.

METHODS: There are very few candidate surface markers that can be used to identify and purify hepatocyte-like cells by using MACS or FACS sorting. In the present study, we tested chemically modified compound for FACS-mediated sorting of hepatocytes after differentiation of various hPSCs established in different institutions.

RESULTS & DISCUSSION: After the final differentiation, differentiated cells and primary hepatocytes (control group) were incubated with a chemically modified compound and were sorted by FACS. Importantly, the chemically modified compound selectively stained cells that expressed albumin. Furthermore, FACS analysis data showed that the purity of hepatocytes that expressed albumin was significantly increased after the purification of chemically modified compound-positive cells.

CONCLUSIONS: Therefore, this compound can be used as a valuable tool to identify and purify stem cell-derived hepatocytes for both in vitro drug screening and in vivo transplantation studies.

Esnchede, The Netherlands

INTRODUCTION: Functional vascularization in engineered tissues is essential for its initial survival after implantation. In this project, we are aiming to study the vascular formation within individual tissue building blocks in two aspects: internal forces, such as cell contractile forces; and external forces, such as shear stress. Studies have shown that more vascular structures formation caused by the tissue contractility tends to happen in regions of higher deformations. We fabricated cell-laden GelMA tissue building blocks with different geometries to investigate how the physical forces generated by cells themselves within a hydrogel environment will induce various contractility. A perfusion device is built to apply an interstitial flow to study how shear stress affects cell orientation, alignment and endothelial sprouting. The primary parameters of the device are set based on computational modelling. By combining the effects of geometries and the patterned interstitial flow through individual tissue building blocks, we can guide the vasculature formation to obtain a tissue with desired properties.

METHODS: GelMA of 82% degree of functionalization (DoF) was synthesised according to the predefined protocols. 7.5% (w/v) GelMA solutions was prepared by dissolving in PBS at 80°C. The concentration of photoinitiator (Irgacure 2959) in the solution was 1% (w/v). A mixture of MSCs and HUVECs at the ratio of 1:1 were loaded into GelMA solution at the concentration of 5 × 10^6 cells/ml. Cell-laden GelMA prepolymer was crosslinked with UV at 365nm wavelength to obtain tissue building blocks. Computational modelling is performed by using COMSOL Multiphysics version 5.3a.

RESULTS & DISCUSSION: Free standing tissue building blocks deform isotropically and more vascular structures were formed in the regions of higher deformation (figure 1). The primary computational modelling results (figure 2) demonstrated that we can pattern and guide cell alignment hence the vasculature formation by applying interstitial fluid flow through individual building blocks.

Figure 1: Deformation of the tissue building block. (A) A cell-laden tissue building block with the geometry of a pentagon was fabricated by photo patterning. (B) Deformation of the tissue building block on day 8 (left). Figure 2: Velocity profile indicates directed fluid flow patterns in tissue building blocks. Flow speed = 0.11m/s, cell experience 5dyn/cm^2 shear stress (right).

INTRODUCTION: Alginate is a natural biopolymer which undergoes rapid gelation in the presence of divalent cations, such as calcium, strontium or barium [1]. This property made it a very popular biomaterial for 3D printing technologies. However, the crosslinked alginate is very unstable in physiological conditions due to substitution of the divalent cations by monovalent sodium. In order to enhance the stability of the printed alginate scaffolds, secondary crosslinking might be performed. Nevertheless, the ion exchange still takes place and leads to release of biologically active cations. The aim of this study was to examine the effect of the secondary crosslinking of alginate 3D fibrous scaffolds on their material and biological properties.

METHODS: Alginate scaffolds were fabricated using Bioplotter (EnvisionTEC) equipped with a custom-made coaxial needle and microfluidic pumps after thorough optimization of the printing parameters (crosslinker molarity, flow rates, XY speed). After printing, the scaffolds were immersed in 0.03M and 0.3M solutions of CaCl₂, SrCl₂ and their mixture for 5 and 30 min. Subsequently, shape fidelity, swelling and mechanical properties were evaluated using confocal microscope, gravimetric and compression test, respectively. The scaffolds were also incubated in cell culture media and the obtained extracts used to study bioactivity with L929 fibroblasts, human mesenchymal stem cells (HMSC) and human umbilical vain endothelial cells (HUVEC) with MTS and alkaline phosphatase (ALP) assays.

RESULTS & DISCUSSION: Application of the coaxial needle enabled fabrication of hydrogel scaffolds with controlled porosity. The time of the secondary crosslinking and molarity of the crosslinking solution had a significant effect on the fiber diameter, mechanical properties and swelling behavior. The released ions did not exhibit any cytotoxic effect. Interestingly, the ALP activity was increased in the HMSC cultured with the extracts. The most pronounced increase (65% higher than in the control, fig. 1) was measured for cells exposed to extracts obtained from the samples crosslinked with CaCl₂/SrCl₂ mixture for 30 min.

CONCLUSIONS: The obtained results suggest that the crosslinking agent for alginate scaffolds might exert a biological effect on the encapsulated cells.

Injectable Hydrogels with self-healing ability for tissue regeneration
J.M.M. Rodrigues¹, A.M.S. Costa¹, J.F. Mano¹
Presenting Author: João M. M. Rodrigues, jrodrigues@ua.pt
¹Department of Chemistry, CICECO – Aveiro Institute of Materials, University of Aveiro, 3810-193 Aveiro, Portugal

INTRODUCTION: Hydrogels, as highly hydrated 3D networks, have proved their potential as body tissue mimics [1,2]. However, the current strategies still fail in obtaining materials with all the following properties: cytocompatibility, injectability, self-healing, mechanical robustness and easy and fast processing [3]. Herein, a novel derivative of laminarin (LAM) polysaccharide was prepared and used to produce hydrogels with potential for Tissue Regeneration purposes.

METHODS: LAM from Eisenia Bicyclis (Carbosynth Limited, UK) was chemically modified to yield the LAM-CAT derivative. First, a nucleophilic substitution of the hydroxyl groups on LAM was done using allyl bromide (Sigma Aldrich). Carboxylic acid groups were incorporated in the former derivative using thiolactic acid (Sigma Aldrich). The previous steps were followed to enable the coupling of dopamine hydrochloride (Sigma Aldrich) to the LAM backbone. Afterwards, the resultant LAM-CAT was purified through dialysis and used to form hydrogels upon adding iron ions (Sigma Aldrich).

RESULTS & DISCUSSION: ¹H/¹³C-NMR spectroscopy and FTIR confirmed the successful functionalization of LAM through a: (i) nucleophilic substitution process using allyl bromide; (ii) thiol-ene Michael addition reaction to incorporate carboxylic acid functional groups; and (iii) EDC/NHS coupling chemistry to attach catechol groups to LAM backbone. Importantly, the developed strategy can be used to modify other polysaccharides with a similar chemical structure to LAM. LAM-CAT polymer was further used to form hydrogels through coordination bonds between the catechol groups presented on LAM-CAT derivatives and Fe³⁺ ions (Figure 1). The hydrogel formation was followed by rheology. Interestingly, the obtained robust hydrogels were formed under mild conditions and were able to self-heal upon rupture and to be administered through minimal invasive techniques. LAM-CAT cytocompatibility was proved by producing cell-loaded hydrogels with high cell viability rates. Other cargos such as sensitive growth factors can also be incorporated within the previous 3D networks.

CONCLUSIONS: LAM-CAT was prepared, characterized and employed to fabricate hydrogels with applicability as cell supporters for tissue engineering, as bioadhesives for diverse biomedical applications and/or as cargo devices for drug delivery.

INTRODUCTION: Thrombosis of artificial cardiovascular implants remains a critical point that hinders successful medical treatment of cardiovascular diseases. Immediately, after contact with blood any foreign surface induces activation of coagulation and fibrin clot formation. Although, there are some improvements still the main challenge faced by many scientists is to totally suppress the acute as well as the late thrombosis of the artificial surface and to promote endothelialization of the implant. Once possibility how to improve the biocompatibility of cardiovascular implants it is coating with fibrin network [1,2]. Fibrin is formed at the place of vessel injury, accumulates various extracellular matrix proteins and growth factors, and by serving as a provisional matrix for numerous cells invading the wound it takes a crucial part in reendothelialization and wound healing.

METHODS: In this study, we present a method of artificial surface modification with a controlled thin layer of fibrin network polymerized from the artificial surface with covalently attached heparin via Schiff base formation and reductive amination. In addition, fibrin network was used for attachment of FGF (Fibroblast growth factor) and VEGF (Vascular endothelial growth factor) via their heparin-binding domains.

RESULTS & DISCUSSION: The amount of heparin and GF was measured by a chromogenic assay and ELISA. Human umbilical vein endothelial cells (EC) were used to test the effect of the coatings on EC viability, growth and morphology. FGF significantly promoted cell growth, especially in higher concentrations, while the effect of VEGF was less visible. The morphology of EC was influenced by the GF. In case of FGF the shape of EC was elongated after 7 days, while with VEGF the cells had a cobblestone-like structure. Best results were obtained when a combination of both GF was used at the same time confirming their synergic effect on the EC.

CONCLUSIONS: Results & In this work, we show that fibrin network can be considered as one of the most versatile coating for various cardiovascular implants. Fibrin-heparin coating inhibits coagulation and together with GF it promotes EC proliferation and differentiation into mature endothelium.

INTRODUCTION: The interface between cartilage and bone is characterized by a gradient of calcium phosphate phases that decline in content from bone towards cartilage. Adipose-derived stem cells are able to differentiate into chondrocytes and osteoblasts, offering the option to use one single cell source for tissue engineering of a biomimetic cartilage/ bone interface.

METHODS: We used an electrospun poly-lactic-co-glycolic acid (PLGA) mesh with incorporated amorphous calcium phosphate nanoparticles in different weight percentages, having a gradient from 30%, 20%, 10% and 0% towards the cartilage mimicking side of the biomimetic interface. The materials were seeded with human adipose-derived stem cells (ASCs) and either cultivated under static conditions or under dynamic conditions in a perfusion bioreactor without any further supplementation of the culture medium. After a total of four weeks, quantitative RT-PCR was performed for eleven relevant genes, including typical marker genes for osteo- and chondrogenesis, but also for adipo- and angiogenesis. In addition, histology and immunohistochemistry was performed to address cell density, proteoglycans and glycosaminoglycans.

RESULTS & DISCUSSION: Under static conditions, the presence of amorphous calcium phosphate nanoparticles did not have any impact on osteo- and chondrogenesis related genes – only CD31 (and endothelial marker gene) was upregulated in the presence of nanoparticles compared to pure PLGA. In contrast, under dynamic conditions, ASCs exhibited an increased expression of chondrogenic marker gene Sox9 towards the cartilage mimicking side. In addition, ASCs showed an increased expression of osteogenic marker gene osteocalcin (OC) towards the bone mimicking side, accompanied by increased OC protein expression. The results found on the gene level were supported by findings on the protein level.

CONCLUSIONS: We conclude that amorphous calcium phosphate nanoparticles incorporated in electrospun PLGA meshes influence the differentiation behavior of human ASCs. Electrospun meshes with gradients of nanoparticles may act as promising cartilage/bone interfaces when cultivated under perfusion in a bioreactor system.

Stem cell-seeded hybrid nanocomposite for chest wall repair in a murine model
Presenting Author: Johanna Buschmann, johanna.buschmann@usz.ch
1Division of Plastic and Hand Surgery, University Hospital Zurich, Switzerland 2Department of Thoracic Surgery, Kyoto University Hospital, Kyoto, Japan 3Institute for Chemical and Bioengineering, Department of Chemistry and Applied Biosciences, ETH Zurich, CH-8093 Zurich, Switzerland 4Division of Thoracic Surgery, University Hospital Zurich, Switzerland, 5Department of Thoracic Surgery, University Hospital Rostock, 18057 Rostock, Germany

INTRODUCTION: Resection of the thoracic wall is a common procedure to remove malignant tumours. Usually, Gore-Tex® is used to replace the missing tissue; however, it is inert and not degradable. Novel biodegradable materials are nowadays available that stimulate and guide the regeneration process. Furthermore, stem cell seeding may help to achieve a good graft integration.

METHODS: A biodegradable bi-layered hybrid nanocomposite material developed, based on poly-lactic-co-glycolic acid and amorphous calcium phosphate nanoparticles (PLGA/aCaP) and pure PLGA. Mechanical properties under dry (time point 0) and wet conditions (time point 2 weeks) were assessed. Electrospun meshes were seeded with murine adipose-derived stem cells (ASCs of C57BL/6). In a mouse model (C57BL/LY5.1), ASC-seeded hybrid scaffolds were implanted as a chest wall graft in order to study biointegration. After 4 and 8 weeks, implant integration towards the skin and the lung, cell infiltration into the bi-layered material, inflammatory responses, neo-vascularization, fibrosis and ECM components (collagen I and fibronectin) were determined in six different zones of the graft.

RESULTS & DISCUSSION: The bi-layered nanocomposite had an ultimate stress of 6 MPa after 2 weeks in DMEM, which was significantly higher than for the pure PLGA/aCaP where it was approximately 0. In vivo, it was very well integrated and cellular infiltration through the whole material was observed. The layer of pure PLGA had shrunk and was visible as “voids” in the H&E stained sections, while the PLGA/aCaP had partially degraded and the fibers were completely surrounded by newly formed extracellular matrix (ECM). In the ECM, collagen I increased from 4 to 8 weeks, for both, the ASC-seeded and the cell-free scaffolds, while the amount of fibronectin was similar at 4 and 8 weeks for both scaffolds. As for the vascularization, the cell-free scaffolds were more vascularized than the ASC-seeded ones at 8 weeks post-operation.

CONCLUSIONS: Hybrid scaffolds of two layers, one with PLGA and one with PLGA/aCaP are superior in terms of mechanical stability than pure PLGA/aCaP. Murine ASCs from C57BL/6 evoked a mild inflammatory response in C57BL/LY5.1 mice when seeded onto the hybrid scaffold. Despite of this reaction, the stable bi-layered scaffold was very well integrated. Although vascularization was higher in the cell-free hybrid scaffold – probably due to space limitation for invading endothelial cells in the ASC-seeded scaffolds where all pores were filled with ASCs –, it was still vascularized homogenously through the whole material, again showing its superior properties when compared to Goretex® which is not vascularized at all.

ACKNOWLEDGEMENTS: We thank Ines Kleiber-Schaaf and Andrea Garcete-Bärtschi for histological and immunohistochemical staining.
From replicative senescence to cell models, diagnostics and therapies of age-associated diseases: stories of translation

INTRODUCTION: Cellular senescence was initially proposed to be an in vitro model of aging, was widely disputed as a mere in vitro artefact but has now been proven to clearly contribute to aging and to the onset and progression of all major age-related diseases including cardiovascular disease, osteoporosis, osteoarthritis, COPD, chronic kidney disease and neurodegenerative disease [1].

METHODS: Our studies aimed at understanding cellular senescence and its contribution to organismal aging as well as counteracting the irreversible growth arrest accompanied by it. During these studies we developed several human, primary cell lines including mesenchymal stem cells immortalized by telomerase [2], a technology that maintains the functions of primary cells, while sufficient cell material for standardized cell based assays or the production of complex biologicals including extracellular vesicles can be produced in standardized conditions. In order to bring these cell lines as well as services including the customer-tailored generation / gene editing of telomerized cells and the establishing of cell based assays to the market we have established Evercyte GmbH in 2011.

RESULTS & DISCUSSION: Furthermore, we identified miRNAs in extracellular vesicles to be secreted by senescent human endothelial cells and to inhibit osteogenic differentiation in vitro [3]. This led to the idea that specific circulating miRNAs might serve as biomarkers for diagnosis of bone diseases, specifically fracture risk assessment. Promising results in this regard led to foundation of TAmiRNA in 2013, the only company world-wide developing signatures of circulating miRNAs towards certified diagnostics outside the field of oncology, specialising in osteoporosis, liver diseases, senescence as well as drug-induced organ-specific toxicology.
Finally, we identified novel potential senolytic drugs, drug that specifically eliminate senescent cells and which are supposed to have major impact on postponing the onset of age associated diseases. A concept to translate these findings within a company to be founded soon is currently developed.

CONCLUSIONS: Within the session on „Academia to industry: building the bridge“ we will showcase and discuss rationale, approach and potential pitfalls of translating scientific insights into products from which patients and society benefit.

INTRODUCTION: Fibrinogen is a naturally occurring protein in the blood and precursor to fibrin which is the end product of blood coagulation. As such, it's a perfect base material for clinically used hemostats and tissue glues. Additionally, it may also act as a local reservoir for growth factors, a matrix for cell growth and can foster regenerative processes in wound healing [1,2]. Autologous-derived fibrinogen would have many advantages for clinical applications as it relieves from the risk of potential biologic contamination in heterologic plasma products.

METHODS: Fibrinogen (sDFib) was extracted from single donor blood plasma bags using 2.2 M glycine and characterized by using BCA assays, polyacrylamide gel electrophoresis, prothrombin-detection and ROTEM thromboelastography.

RESULTS & DISCUSSION: We could isolate fibrinogen at concentrations > 20g/L (20.6g/L mean), comparable to commercial fibrinogen concentrates like Haemoclompettan P (CLS Behring). No further impurities (such as prothrombin) were detected in sDFib. No significant differences in clotting time compared to fibrinogen from Tisseel, Baxter were observed.

CONCLUSIONS: We have developed a method to isolate a concentrated fraction of autologous or single donor allogeneic fibrinogen (sDFib). Our isolation procedure would be capable to be manufactured in a closed container system and may be useful for transfusion to become a new alternative to current pooled fibrinogen products for patients.

INTRODUCTION: Management of significant facial bone defects or asymmetry are challenging. Conventional options include autogenous bone grafts or alloplastic implants. However, bone grafts are limited by donor morbidity, unpredictable results and long operation time. Alloplastic implants are mainly non-absorbable and may cause foreign body reaction. We present the application of a 3D-printed patient specific absorbable mesh implant for reconstruction of bone defect caused by tumor resection.

METHODS: A customized polycaprolactone (PCL) scaffold was designed and fabricated for each patient. For this purpose, we used computer-aided design and manufacturing combined with 3D printing technology. The patients implanted with the PCL scaffolds were followed up for up to 2 years with careful evaluation of morphological changes in the face. We have experienced 5 more clinical case of craniofacial reconstruction with patient specific 3D printed implant.

RESULTS & DISCUSSION: We confirmed that the patient-specific 3D-printed PCL scaffold effectively filled the maxillary defect and promoted regeneration of the deficient tissue while remaining stable in the body for a relatively long period of time.

CONCLUSIONS: Employing customized tissue-engineered scaffolds built using the patient's CT data and an extrusion-based 3D printing system is safe and clinically feasible, helping create and maintain improved morphological features of the face, which represents the most important aspect from the perspective of the patients.

INTRODUCTION: Peripheral nerves can regenerate spontaneously after damage, however, their regeneration ability is limited and functional deficits would be continued following major peripheral nerve injuries [1]. The nerve defects exceeding 5mm have been treated with autologous nerve grafts, allografts or hollow tube type nerve conduits in clinical settings, but complete functional recovery has seldom been reported [2]. Herein, we developed a nerve conduit containing intraluminal structure with unidirectional microchannels to give a physical cue for outgrowing axons of peripheral nerves, and applied the conduit to rats with long defect in the sciatic nerve.

METHODS: To develop microchannels within a nerve conduit, phosphate glass fibers were used as frames, and dissolved poly (lactic-co-glycolic acid) (PLGA) or polycaprolactone (PCL) was filled microchannels. Nerve growth factor (NGF) was also internalized into heparin-treated nerve conduit whether NGF may enhance axonal regeneration in addition to microchannel structure. Lewis rats were used, and 16mm-nerve gap was created after unilateral sciatic nerve transection. Three experimental groups, which received PLGA (PLGA group), PLGA with NGF (PLGA+NGF group), or PCL nerve conduits (PCL group) respectively, and two control groups, which was performed autograft (autograft group) or received hollow tube without intraluminal structure (hollow group), were compared each other until 16 weeks after implantation.

RESULTS & DISCUSSION: All experimental and control groups showed gradual motor and sensory recovery until sacrifice. The number of axons at the proximal end of distal stumps 16 weeks after implantation were higher in autograft and PCL groups than in any other experimental and control groups, and there was no difference between autograft and PCL groups. The sciatic static index, sciatic functional index, thermal sensory test also showed that the motor and sensory recovery was prominent in autograft and PCL groups than in other experimental and control groups from 11 weeks to sacrifice.

CONCLUSIONS: Our new microchannel-based nerve conduit, especially PCL-based, is effective for axonal regeneration after peripheral nerve injury, and nerve growth factor did not show any synergistic effects for nerve regeneration. We conclude that our PCL nerve conduit might substitute for autograft after peripheral nerve transection injury.

A novel, rapid and cost-effective method for separating drug-loaded liposomes
J. Jose¹, V. Muthuvijayan¹
Presenting Author: Joseph Jose, josephjosekanichai@gmail.com
¹Department of Biotechnology, Bhupat and Jyoti Mehta School of Biosciences, Indian Institute of Technology Madras, Chennai, India

INTRODUCTION: Liposomes are the first nano-scale drug delivery systems that have been transformed into successful clinical products. Over the past few decades, a great deal of work has gone into innovating, improving, and perfecting several aspects of the liposomal drug delivery system. Separating the drug-loaded liposomes from the free drug is an integral part of producing liposomal drug formulations. Conventionally, this separation is achieved using techniques like, ultracentrifugation, chromatography or dialysis. All these methods have their drawbacks, such as cost, scalability and efficiency [1][2][3]. The objective of this work is to develop a simpler, cheaper, and easily scalable technique to perform this separation step.

METHODS: Liposomes were successfully synthesised and precipitated out using different solvents. The efficiency of this separation was compared to other conventional techniques like ultracentrifugation and ultrafiltration. The morphological integrity of the precipitated liposomes was confirmed using dynamic light scattering and electron microscopy. The release profile of doxorubicin from these precipitated liposomes was compared to liposomes separated by the conventional methods.

RESULTS & DISCUSSION: This novel precipitation technique was able to separate almost 100% of the liposomes (Figure 1). The structural integrity of the liposomes was found to be preserved, even after precipitation step. The release profile of doxorubicin from the liposomes separated by different techniques (solvent-based precipitation, ultracentrifugation and ultrafiltration) was found to be similar.

CONCLUSIONS: This novel method proves to be an efficient, convenient and a simpler technique to separate liposomes from the free drug compared to conventional techniques.

INTRODUCTION: Low back pain affects 80% of the population at some point in their lives with 40% of cases attributed to intervertebral disc (IVD) degeneration. There are many animal models to investigate IVD degeneration, such as murine and porcine models. However due to significant differences in physiology between these types of models and humans, such as the preservation of notochordal cells into adulthood, they are not completely representative of the human condition. Therefore, a more representative large animal model for IVD degeneration is needed to mimic human degeneration. Here we investigate a caprine IVD degeneration model for its use in testing our synthetic, Laponite® cross-linked pNIPAM-co-DMAc, injectable hydrogel (NPgel). NPgel has been shown to induce differentiation of human MSCs (hMSCs) towards a nucleus pulposus (NP) cell phenotype without the need for additional growth factors in vitro [1]. Through utilising the caprine model of IVD degeneration we aim to validate whether the NPgel retains these characteristics in vivo.

METHODS: After three days of culture in a bioreactor under diurnal, simulated-physiological loading (SPL) conditions, 33 healthy lumbar caprine IVDs were degenerated enzymatically by injecting 50 uL of 1 mg/mL collagenase and 2 U/mL chondroitinase ABC (cABC). After injection, the IVDs were subjected to SPL again after two hours of digestion, for another 10 days. A no-intervention and phosphate buffered saline (PBS) injected group were used as controls. Disc deformation was continuously monitored and changes in disc height recovery behaviour were quantified using stretched-exponential fitting. Histological staining was performed on caprine discs to assess extracellular matrix (ECM) production and immunohistochemistry (IHC) was performed to determine expression of catabolic protein expression. Following establishment of the IVD model, NPgel was injected into goat IVDs and similar tests performed.

RESULTS & DISCUSSION: The injection of collagenase and cABC had severe effects on the mechanical behavior of the IVDs, especially in time constants and creep behaviour (Figure 1). These changes were progressive over time. Histological staining identified a decrease in ECM components such as collagens and glycosaminoglycans (GAGs) in enzyme injected discs. IHC identified an increase in degradative enzymes such as MMP3, MMP13 and ADAMTS4 and a decrease in aggrecan and collagen II also in enzyme treated discs.

CONCLUSIONS: Here we show a novel, reproducible large animal model of IVD degeneration which mimics IVD degeneration. This model allows the testing of biomaterials and other potential treatments of IVD degeneration on a scale more representative of the human disc than more commonly used murine and porcine models. The development of treatments for IVD degeneration is hindered using models which do not closely represent human IVD degeneration. Here we have established a reproducible, large animal model of IVD degeneration that has the potential for use in the screening of biomaterials and other treatments for IVD degeneration.

Differentiation of mesenchymal stem cells in an injectable hydrogel under the conditions of the degenerate intervertebral disc

J. Snuggs¹, A. Thorpe¹, C. Hutson¹, S. Partridge¹, C. Sammon¹, C. Le Maitre¹
Presenting Author: Joseph Snuggs, J.Snuggs@shu.ac.uk
¹Sheffield Hallam University, Sheffield, UK

INTRODUCTION: Low back pain affects 80% of the population at some point in their lives with 40% of cases attributed to intervertebral disc (IVD) degeneration. IVD degeneration is caused by a cascade of cytokine and catabolic enzyme production leading to the destruction of extracellular matrix (ECM) and irreversible alterations to the disc microenvironment, which all contribute to the loss of IVD function. We have previously reported the development of NPgel, a synthetic, Laponite® cross-linked pNIPAM-co-DMAc, injectable hydrogel. NPgel has been shown to induce differentiation of human MSCs (hMSCs) towards a nucleus pulposus (NP) cell phenotype without the need for additional growth factors in vitro and also fully integrates with NP tissue following injection into the disc. However, the translation of this potential treatment strategy into a clinical application is dependent on the survival and differentiation of hMSCs into the correct cell phenotype within the degenerate IVD. Here, we investigated the viability and the differentiation of hMSCs incorporated into NPgel cultured under conditions mimicking the healthy and degenerate disc.

METHODS: Human MSCs were cultured in monolayer before encapsulation into NPgel, at a density of 4x10⁶, and cultured for up to 4 weeks in 1 of 4 treatment groups (n=3). Each group mimicked conditions from, standard culture (DMEM, pH7.4), healthy disc (DMEM, pH7.1), degenerate disc (low glucose DMEM, pH6) or degenerate disc plus 10ng/mL IL-1β. All culture was performed at 5% oxygen concentration. MSCs were also collected at time-point 0h prior to treatment to serve as controls. Cell viability was assessed by immunohistochemistry for the apoptotic marker, cleaved caspase-3. Histological staining and immunohistochemical analysis investigated ECM synthesis and matrix degrading enzyme expression, specifically MMP3, MMP13 and ADAMTS4. Differentiation capacity of the human MSCs was determined using immunohistochemical analysis for NP extracellular matrix markers collagen type II and aggrecan.

RESULTS & DISCUSSION: Viability of hMSCs was maintained in NPgel; the immunopositivity of caspase-3 was increased in degenerate conditions, but >60% of cells in all treatment groups were viable after 4 weeks of culture. Collagen II and aggrecan immunopositivity increased over the culture period and levels were comparable between healthy and degenerate disc conditions. Expression of degradative enzymes remained low across all treatment groups for the culture duration and masson trichrome and alcian blue staining also confirmed the deposition of matrix within the NPgel scaffolds.

CONCLUSIONS: In agreement with our previous findings¹,² NPgel was able to induce NP cell differentiation of MSCs, with expression of both aggrecan and collagen type II under standard culture conditions. Here we have shown that viability and NP cell differentiation of MSCs incorporated within NPgel was mostly unaffected by treatment with conditions such as low glucose, low pH and the presence of cytokines, all regarded as key contributors to disc degeneration. In addition, the NPgel was shown to prevent MSCs from displaying a catabolic phenotype with low expression of degradative enzymes, highlighting the potential of NPgel to differentiate hMSCs and protect them from the degenerate disc microenvironment. The NPgel described here not only has the potential to provide mechanical support and deliver MSCs for regeneration of the IVD but also may function to protect delivered hMSCs from the catabolic environment in the degenerate IVD.
ALK5 is essential for tooth germ differentiation during tooth development
W. Guo1, J. Du1

1Laboratory of Molecular Signaling and Stem Cells Therapy, Molecular Laboratory for Gene Therapy and Tooth Regeneration, Beijing Key Laboratory of Tooth Regeneration and Function Reconstruction, Capital Medical University School of Stomatology, Beijing 100050, China

INTRODUCTION: The TGFβ superfamily of proteins participates in tooth development. TGFβ1 and TGFβ3 regulate odontoblast differentiation and dentin extracellular matrix synthesis [1]. Although the expression of TGFβ family member ligands is well-characterized during mammalian tooth development, less is known about the TGFβ receptor, which is a heteromeric complex consisting of a type I and type II receptors. The molecular mechanism of ALK5 (TGFβR1) in the dental mesenchyme is not clear.

METHODS: Tooth germ mesenchymal cells (TGMCs) from the lower first molar tooth germs of day 15.5 embryonic mice were harvested. Human recombinant TGFβ3 protein or an ALK5 inhibitor (SD208) was added to the cells. Cell proliferation was investigated by CCK8 assay, and Alizarin red staining and osteogenic and dentinogenic marker genes which were measured by real-time RT-PCR were checked to investigate the cell osteogenesis/dentinogenesis. The expressions of both canonical and noncanonical TGFβ signaling pathways genes were observed by real-time RT-PCR and western blot.

RESULTS & DISCUSSION: The number of cells was reduced significantly in the SD208 group compared to the control group at 1 and 2 days, whereas the TGFβ3 group exhibited an increased number of cells at 1 and 2 days. After 2 days, the cells clearly had differentiated and grew slowly. Alizarin red staining indicated that inhibition of ALK5 markedly decreased mineralization, whereas TGFβ3 increased mineralization of TGMCs. The optical density due to alizarin red in cultured TGMCs increased mineralization in the TGFβ3 group (p < 0.05) and decreased it in the SD208 group (p < 0.05) compared to the control after cell culture for 14 days. Osteogenic and dentinogenic markers, Dspp, Dmp1, Bsp, Ocn, Opn were increased significantly by TGFβ3 and decreased significantly when ALK5 was inhibited for 7 and 14 days compared to the control group (p<0.05). We also found TGFβ3 activated ALK5 and Smad4 and SD208 inhibited ALK5 and Smad4 during TGMCs osteogenesis and dentinogenesis. And inhibition of ALK5 increased the expression of P-TAK1 protein slightly (Figure 3E) and up-regulated P-p38 protein levels in TGMCs after culture for 24 and 48 h.

CONCLUSIONS: We found that TGFβ3/ALK5 signaling regulated the osteogenesis and dentinogenic differentiation potential of TGMCs by both Smad4-dependent and p38 protein kinase signaling pathways. Our findings suggest that both Smad4 and p38 MAPK may be possible targets for optimizing the use of stem cells of dental origin for application to tissue regeneration.

Optimisation of gelatin crosslinking in bicomponent electrospun nanofibres with the use of EDC/NHS

J. Dulnik, P. Sajkiewicz
Presenting Author: Judyta Dulnik, jdulnik@ippt.pan.pl
Laboratory of Polymers and Biomaterials, Institute of Fundamental Technological Research, Polish Academy of Sciences, Warsaw, Poland

INTRODUCTION: Introducing gelatin into synthetic polymeric materials has unquestionable advantages for tissue engineering. In our previous studies we have demonstrated the feasibility of using nontoxic solvents for electrospinning of polycaprolactone/gelatin (PCL/Gt) blends [1], as well as a necessity of preserving the biopolymer within the fibre due to its susceptibility to dissolution in hydrous environment [2].

Looking for a compromise between cheap, fast and low toxic, a set of four crosslinking agents were examined during preliminary studies. EDC/NHS (1-ethyl-3- (3-dimethylaminopropyl) carbodiimide hydrochloride/N-hydroxy-succinimide) method proved to meet best our requirements.

METHODS: A broad set of varying conditions was established based on the results of EDC/NHS preliminary results. Electrospun materials with different PCL/Gt ratios were subjected to crosslinking with EDC/NHS solutions with varying concentrations for periods ranging from 1 to 9 hours. All samples underwent biodegradation studies, crosslinking degree tests, SEM imaging, as well as wettability and mechanical properties examination.

RESULTS & DISCUSSION: Analysis of gelatin crosslinking results, showed that the kinetics of the process is very fast at the beginning followed by slow stage at longer time of the process. The critical time, needed to get 85% of crosslinked gelatin, is a function of EDC/NHS solution concentration, being the shorter the higher is this concentration.

CONCLUSIONS: EDC/NHS method gives an operator the freedom in setting out crosslinking conditions since time and solution concentration are inversely interchangeable. For any studied conditions, this method gives satisfactory crosslinking degree cheaper and faster than any of its competition.

INTRODUCTION: Currently used polymeric resorbable and non-resorbable materials possess many structural, mechanical and bio-functional limitations. The use of biodegradable polymers in a form of fibrous meshes fabricated via electrospinning method are good choice to overcome these limitations due to the flexibility in the use of the components and various morphologies of the fibres [1]. The introduction of components like nanohydroxyapatite (nHA) have been proved to enhance bone tissue regeneration and neutralize material degradation, which would favour the regeneration of lost tissues. Therefore, electrospinning and application of nHA deposition on fibres were proposed to meet challenging clinical criteria [2].

METHODS: Electrospun fibrous meshes prepared from PDLLA and PLGA polymers were used as a base structure material. Coating of the fibrous structure with nHA particles was performed in aqueous solutions as a two stage ultrasonic process according to the patent [3]. We used two types of highly biocompatible hydroxyapatite ceramic nanoparticles (15nm and 45nm) for implant fabrication. It was proved that surface application of ceramic nanoparticles of high specific area can significantly increase water contact angle and cellular activity on the fibrous implants.

RESULTS & DISCUSSION: As a result of process induced nearby the textile substrate nanohydroxyapatite uniform layers of 150-200nm thickness were obtained on polymeric fibres. Scanning Electron Microscopy imaging revealed that nHA particles cover fibres but do not interfere with the structure of the base material. The porous structure of fibrous mesh was maintained practically unchanged and wettability of the material was highly increased.

CONCLUSIONS: The novel non-destructive method of nHA deposition on the fibres can serve as an alternative for currently used implant modification methods and enhance the bone regeneration process in bone/implant interface region. The method of coating have been proved to be suitable for coating highly porous, thermally and mechanically sensitive materials.

INTRODUCTION: In tissue engineering and regenerative medicine, one main limitation prevents the development of thick engineered tissue: the lack of vascularization. Indeed, cells located at more than 200µm from blood vessels cannot survive because they do not receive enough nutrients. To overcome this problem, in vitro prevascularization strategies can be considered. In this project, we have used 3D printing strategy to fabricate a Pluronic sacrificial network in the shape of a lattice of 6 layers of material. Then this Pluronic scaffold was filled with gelatin hydrogel and put at 4°C to dissolve Pluronic network. With this strategy, we obtained a gelatin hydrogel with hollow channels that was demonstrated to be colonized with endothelial cells to create an initial vascular network.

METHODS: 3D printer has been used to print Pluronic scaffold. Multiple parameters were considered such as extrusion pressure, feed rate, nozzle diameter and Pluronic concentration to define the printability window and to obtain the expected channel dimensions. The diameter of the extruded material was assessed with SEM and numerical microscope. Once printed, Pluronic scaffold was filled with gelatin type A solution and then the hydrogel was enzymatically crosslinked with microbial transglutaminase at 4°C. During this last step, Pluronic scaffold was evacuated from the gelatin structure since it is liquid at this temperature. Endothelial cells were then used to colonize the scaffold and develop a vascular network. Immunostaining (PECAM CD31) and biochemical assay (Alamar Blue) were used to characterize endothelial marker and cell viability within the hydrogel.

RESULTS & DISCUSSION: To keep cells located less than 200µm from blood vessels and to obtain blood vessels of 500µm diameter, it was shown that the best design was a lattice structure composed of extruded materials of 300µm diameter with a horizontal spacing of 1mm between two rods. If the spacing was less than 1mm, the filling with gelatin material was inhomogeneous due to a structure too tight. A new design was also proposed to prevent the fusion between two layers of materials, it was demonstrated that the distance between two horizontal lines should be at least 600 µm to prevent any collapse of the structure. The final design (double rod) is presented in figure 1. The best reproducibility was achieved with a concentration of 30wt% of Pluronic. The final structure was then filled with gelatin hydrogel and successfully colonized with endothelial cells where endothelial cells form dense layers at the inner surface of lattices.

CONCLUSIONS: This project demonstrates the importance of design and the control of printing and material parameters to develop prevascularized hydrogels.

Figure 1: Different Pluronic scaffold designs to obtain the best sacrificial network.

INTRODUCTION: Neurotrophic factors (NTFs) have potential to promote neuronal regeneration and concomitant functional restoration in central and peripheral nervous systems [1-3]. We previously developed microchannel-containing scaffolds for spinal cord regeneration, and found outgrowing axons were observed within the scaffold, however, functional improvement was not detected. Herein, we internalize three types of NTFs into our microchannel scaffold to enhance axonal regeneration after complete transection of spinal cord in rats.

METHODS: Three NTFs; neurotrophin-3 (NT-3), glial cell-derived neurotrophic factor (GDNF), and ciliary neurotrophic factor (CNTF) with various concentrations (from 0.5 to 10.0 μg/ml) were added respectively into the heparin-immobilized microchannel scaffolds. The spinal cord at T9 level in Sprague-Dawley rats was completely transected and removed, and 5mm-long NTF-coated scaffold was inserted into the gap between the proximal and distal stumps just after transection injury. The spinal cord transected rats which did not receive the scaffold, and those received the scaffold without NTFs were considered as controls.

RESULTS & DISCUSSION: According to the immunohistochemical findings, the outgrowing axons were visible in both sides of the scaffold in all experimental groups and control which received scaffold without NTFs 2 weeks after implantation. The maximal length of outgrowing axons from both sides of the stump was longer in 2.5 μg/ml GDNF-containing scaffold received group (2.5 GDNF group) than in other experimental and control groups. Interestingly, the regeneration of afferent pathways was increased more than the efferent pathways when GDNF-containing scaffold was used. In addition, the amount of axons and astrocytes within the scaffold was greater in 2.5 GDNF group than in other experimental groups. The locomotor recovery was prominent in 1.0 and 2.5 GDNF groups more than in other experimental groups and controls 12 weeks after implantation.

CONCLUSIONS: Among three NTFs, GDNF was the most effective to promote axonal outgrowth crossing the microchannel-containing scaffold which was implanted within the transected spinal cord in rats. We concluded the optimal concentration of GDNF might have a synergistic effect to induce axonal regeneration and functional improvements as well as the physical guidance of microchannels within the scaffold following complete transection injury of spinal cord in rats.

Silk fibroin/gelatin film incorporating antibiotic silver sulfadiazine for medical application
P. Umprasert, J. Ratanavaraporn
Presenting Author: Juthamas Ratanavaraporn, juthamas.r@chula.ac.th
Biomedical Engineering Program, Faculty of Engineering, Chulalongkorn University, Patumwan, Bangkok 10330, Thailand

INTRODUCTION: Silk fibroin, a protein derived from cocoons of Bombyx Mori silkworms, has excellent mechanical properties and slow degradation rate while generates minimal inflammatory and immune responses [1]. Gelatin, a denatured collagen, possesses biocompatibility and Arg-Gly-Asp (RGD) sequence to promote cell attachment and proliferation [2]. The blending of silk fibroin/gelatin improved mechanical properties due to the silk fibroin component while enhanced the biological activities by the gelatin component [3]. In this study, the silk fibroin/gelatin mixture was formed into film and incorporated with a cationic antibiotic silver sulfadiazine. Concentration of silver sulfadiazine was optimized to suit the medical application.

METHODS: The regenerated silk fibroin solution was prepared following the method previously reported [3]. The silk fibroin solution was mixed with gelatin solution at a weight ratio of 50/50. Various concentrations of silver sulfadiazine (0, 0.12, 0.62, 1.16, 1.69, and 2.16%wt/wt) were added to the silk fibroin/gelatin solution and stirred for 10 min at 25°C. Then, the mixture was cast in a mold and air-dried at ambient temperature under darkness. Gel fraction, swelling ability, cytotoxicity and anti-bacterial activities of the silk fibroin/gelatin films incorporating silver sulfadiazine were characterized.

RESULTS & DISCUSSION: The silk fibroin/gelatin films incorporating silver sulfadiazine at every concentration showed a slight reduced swelling ability but higher gel (water-insoluble) fraction when compared to the silk fibroin/gelatin films without silver sulfadiazine incorporation. We also proved that the release of silver sulfadiazine from the films incorporating 1.16 and 2.16% silver sulfadiazine potentially inhibited the growth of both gram-positive and gram-negative bacteria while the toxicity to L929 mouse fibroblast cells was not found.

CONCLUSIONS: The silk fibroin/gelatin films incorporating 1.16% silver sulfadiazine was suit to medical application because it showed potential anti-bacterial activity and non-cytotoxicity to normal cells while the water swelling ability and stability were sufficient.

Are cyclic stretch-induced cell and nucleus deformations mechanical input-energy-dependent?

K.S. Strobel¹, J. Stegemann², B. Walters², B. Rolauffs¹

Presenting Author: Kai S. Strobel, reno655@hotmail.com

¹G.E.R.N. Tissue Replacement, Regeneration & Neogenesis, Dept. of Orthopedics and Trauma Surgery, Albert-Ludwigs-University of Freiburg, Hugstetter Straße 55, 79106 Freiburg, German; ²Dept. of Biomedical Engineering, University of Michigan, Michigan, MI 48109, USA

INTRODUCTION: How physical stimuli are perceived by cells is increasingly relevant for controlling cell behavior, and the nucleus is emerging as an important cellular mechanosensor. Since cell morphology and behavior can be influenced using mechanical stretch [1] and this has been shown to be input energy-dependent [2], our hypothesis was that changes in nucleus shape share this dependency, and that it correlates with cell behavior.

METHODS: Human mesenchymal stromal cells (MSCs) isolated from bone marrow were cultured on fibronectin-coated polyacrylamide hydrogels (10%, 0.4% bisacrylamide) for 4 days. The seeded gels were then transferred to an incubator-housed ElectroForce 5210 BioDynamic-Test-System, where sinusoidal stretch experiments with a range of increasing energy inputs were performed. Calcein/DAPI imaging was used with in-house cell segmentation tools to assess morphology (imageJ). mRNA was isolated, transcribed to cDNA and RT-PCR was used to measure expression (ACTA, TGLN, CNN and DES). Correlations were assessed using Pearson Product-Moment Correlation and Partial Least Squares (PLS) analysis.

RESULTS & DISCUSSION: Pearson correlation showed nuclear length, area and roundness correlated respectively to that of the cell (ρ  = 0.171, 0.393 and 0.283). Nucleus solidity correlated directly with the logarithm of energy input (ρ = -0.01). PLS analysis of nucleus solidity revealed that energy had a low regression coefficient (β = 0.357) when compared to other variables, where the strain amplitude was more strongly correlated (β = 0.830).

CONCLUSIONS: Pearson correlation between energy input and nucleus solidity was small, but mechanical nuclear deformations are generally small (eg [3]), suggesting the small correlation is due to small changes in morphology. While PLS revealed strain amplitude to have higher correlation with solidity than log energy, both parameters positively correlated and amplitude is a contributing variable to the energy input term. In conclusion, small changes in nuclear solidity can be correlated to the log of energy input, with the determining factor being the strain amplitude.

INTRODUCTION: Regeneration after spinal cord injury is a goal of many studies. Though the most obvious target is to recover motor function, sensory regeneration can improve quality life in paraplegic patients. According to a patient’s survey, recovery of sensation in the perineal and genital area is one of the highest priorities. Although there are behavioural tests to measure sensitivity, there is no test for measuring sensation in perineal and genital area. The aim of our study was to develop the behavioural test for measuring the sensitivity of perineal and genital area in rats.

METHODS: We have modified the tape removal test used routinely to test sensorimotor deficits after stroke. We adapted the test to perineal area and tested several settings. A small piece of tape (approximately 1 cm²) was attached to perineal area on the left side. Time to first touch and to remove the tape was measured. If the rat didn’t remove the tape until 5 minutes the tape was removed and the time of 5 min was recorded. This was repeated 4 times for each animal with 3 min pause between each trial. Each rat was trained in 5 consecutive days and then tested weekly. We compared different rat strains (Wistar, Sprague-Dawley, Long-Evans and Lewis), both genders, shaving and non-shaving and different types of tapes. All tests were performed on healthy animals and animals with T10 dorsal hemisection. After the spinal cord injury animals tested at day 3, 8, 14 and 21.

RESULTS & DISCUSSION: We found that the test was suitable for all tested strains, however, the Lewis rats achieved the lowest contact times. But this difference was significant only in first few days of learning the task. There were no significant differences between gender and different types of tape or shaving. After the animals underwent dorsal hemisection the test could detect sensory deficit, the time to sense the stimulus increased from 1’32 up to 3’20 in average. This was compared with other behavioural tests (BBB, von Frey, ladder and Plantar test). Animals were divided according to the lesion size to big, medium and small lesion groups. Whilst deficits detected in tape test correlated with the size of the lesion, von Frey and Plantar tests showed only non-significant deficit independent on the lesion size.

CONCLUSIONS: We conclude, tape removal test is suitable for testing perineal and genital sensation in rats and can be used in different strains.

INTRODUCTION: Non-traumatic spinal cord injury (NT-SCI) involves spinal cord stenosis which increases over months to years; as opposed to the millisecond duration of traumatic spinal cord injuries. Despite affecting up to 150000 people in the UK1, NT-SCI pathology is poorly understood. This research aims to develop experimental models of NT-SCI in order to better understand the neural cell responses to low-velocity mechanical insults.

METHODS: In-vitro, primary rat astrocytes isolated from P3 pre-weaner rats were seeded into rat collagen I (1.6 mg.mL⁻¹) hydrogels at 1x10⁶ cells.mL⁻¹ of gel. Gels were compressed to 70% of their height using a BOSE Electroforce 5110 Biodynamic, at 0.1 to 100 mm.s⁻¹. Positive control included supplementing with 10 ng.mL⁻¹ TGF-β2,3. Immuno-labelling for GFAP was carried out over 14 days.

RESULTS & DISCUSSION: On day 1, there was no significant difference in GFAP area or cellular circularity between experimental groups. On day 14, GFAP area was significantly greater in TGF-beta treatment and 100 mm/s velocity groups than in the 0.1 mm/s group (p < 0.05). Similarly on day 14, circularity was significantly greater in the 0.1 mm/s group compared to 100 mm/s and TGF-beta treated groups (p < 0.05). This reflects the increased ramification of cells compressed at 100 mm/s, and with TGF-beta treatment.

CONCLUSIONS: Preliminary findings indicate methods to model NT-SCI in-vitro have been established. Evaluation of images indicate astrocyte reactivity is increased at 14 days with TGF-beta treatment or compression at a traumatic velocity (100mm/s). However, in NT-SCI (0.1 mm/s) the astrocytes do not behave in the same manner. Further studies will be undertaken to evaluate other markers of astrocyte function, such as ELISA. Better understanding of cellular behavior in NT-SCI will allow improved disease management and therapeutic development

INTRODUCTION: Decellularized natural matrices provide an alternative platform in tumor tissue engineering for its biomechanical characteristics and tissue-specific ECM composition. Herein, we introduced an organotypic 3D breast cancer model in vitro using decellularized porcine lung and evaluated the 3D cell behaviors and protein expression of breast cancer specific markers.

METHODS: A total of 50 μL cell suspensions at a density of 2× 10⁶ cells/ml were seeded on both sides of each scaffold in 24-well plates. Immunofluorescence of F-actin was detected to investigate cell distribution in lung scaffolds. Dead/Live staining was conducted to assess cell viability in decellularized lung scaffolds. SEM was conducted to evaluate cell growth. Besides, Immunofluorescence and flow cytometry assays were conducted to evaluate the expressions of hypoxia-inducible factor 1 α (HIF1α), breast cancer susceptibility gene 1 (BRCA1) and human epidermal growth factor receptor 2 (HER2) of cells cultured in 2D or 3D lung scaffolds.

RESULTS & DISCUSSION: F-actin immunofluorescence showed cell closely adhered to the skeleton of lung scaffold, and the porous of scaffold was easily identified. Dead/Live indicated favorable viability of cells, suggesting good cell compatibility of the decellularized lung scaffolds. SEM showed cells gradually developed into multilayers and tumoroids that merged with surrounding cell colonies over time (Figure 1a). The stronger expression of breast cancer-related markers suggested that cells in lung scaffolds displayed higher malignancy as compared to those in 2D cultures (Figure 1b-c).

CONCLUSIONS: Collectively, these data indicate that the organotypic-derived lung scaffold coupled to human cancer cells better simulate the native tumor microenvironment that favors cell progression and higher malignancy.

Figure 1: Cell behavior and protein expression of breast cancer markers in 3D lung scaffold. (a) Cell distribution, viability and proliferation in 3D scaffold. (b) Protein expression of BRCA1, HER2 and HIF1α in 2D and 3D lung scaffolds by IF and flow cytometry.

INTRODUCTION: Monocyte activation test (MAT) is emerging alternative to LAL test and rabbit pyrogen tests [1-2]. Its benefits include in vitro procedure with no need for animals and more relevant response of human immune system comparing to crustacean based LAL test. In this work we have established the procedure of testing slowly hyaluronan (HA) preparations and biodegradable HA-based materials by MAT.

METHODS: Heparinized or citrated human blood was drawn from 4-5 donors (with their informed consent) for every test and assayed within 3 h. Materials both soluble and not-readily soluble were assayed in normal saline at 1-10 mg/ml concentration. Extracts were prepared in saline or media under constant agitation for 24-72 h at 37 °C. Samples were incubated with pooled blood overnight and plasma was then assayed for IL-6 cytokine by ELISA (eBioscience). Samples used for MAT evaluation included: HA of high molecular weight (HMW) - pharmaceutical and cosmetic grade, HA fragments prepared by enzymatic degradation, HA derivatives and HA-based biomaterials.

RESULTS & DISCUSSION: MAT itself was optimized comparing individual donor or pooled blood. The variability among donors proved problematic, thus whole blood pooled from 4-5 donors was used for subsequent experiments. For samples with low or none added Ca2+ the heparinized blood was used. The citrated blood necessary for Ca2+-containing biomaterial samples as added Ca2+ started to the coagulation spontaneously. The specificity and sensitivity of MAT was tested using endotoxin standard (0.1-10 IU/ml) and non-endotoxin pyrogen (lipoteichoic acid, LTA). The native HMW HA (pharma grade) showed no pyrogenic response in good concordance with standard LAL test. Low-endotoxin cosmetic HA showed increased response to LPS spike suggesting the presence of non-endotoxin contaminants (Fig. 1), such as glucans and LTA. HA-based biomaterials were tested as solutions or extracts and MAT was able to detect pyrogens with the limit of 0.25 IU/mg which is sensitive enough for evaluation of pyrogenity of medical devices.

CONCLUSIONS: MAT using whole human blood is good alternative or addition to classic pyrogen testing methods, providing better insight to pyrogenity of complex biomaterials.

INTRODUCTION: Repair and healing fractures caused by osteoporosis still remains a major clinical challenge in orthopaedic surgery [1]. In recent years, fabrication of hydrogels mimicking the natural extracellular matrix of the bone has attracted research interest in the field of hydrogel-based bone regeneration [2]. The aim of this study is to develop novel bioactive composite hydrogels based on nanosized hydroxyapatite and natural biopolymers ε-polylysine and hyaluronic acid.

METHODS: Bioactive hydrogel system based on nanosized hydroxyapatite (n-HAp), ε-polylysine (ε-PL) and hyaluronic acid (HA) was prepared using in situ synthesis of n-HAp in ε-PL solution and via chemical cross-linking using the carbodiimide (EDC) and N-hydroxysuccinimide (NHS) (molar ratio of EDC/NHS 1:1; weight ratio of n-HAp and ε-PL/HA 50:50, 70:30 wt.%). The EDC and NHS were added into an in-situ synthesized n-HAp/ε-PL solution and cooled at 4 °C. The HA was added into a synthesized n-HAp/ε-PL solution. The n-HAp/ε-PL/HA hydrogel would be produced after rapid stirring within less than 5 min. The composition, purity and microstructure of all synthesized samples will be evaluated using powder X-ray diffractometry (XRD), Fourier transformation infrared spectrometry (FTIR) and scanning electron microscopy (SEM). Investigation of swelling properties in phosphate buffer saline (PBS), the surface and cross-section morphologies before and after immersion tests was performed.

RESULTS & DISCUSSION: SEM micrographs revealed that the freeze-dried n-HAp/ε-PL/HA hydrogels were highly porous and consist of interconnected pores. SEM and XRD results demonstrated formation of n-HAp phase which incorporates into the ε-PL macromolecules. FTIR spectra proved that hydrogels were crosslinked through amide bond linkage. The gelation time in the crosslink process of n-HAp/ε-PL/HA hydrogels was within less than 5 min. The obtained hydrogels were successfully sterilized by autoclave sterilization.

CONCLUSIONS: The development of bioactive composite hydrogel system based on nanosized hydroxyapatite, ε-polylysine and hyaluronic acid was done. Considering the beneficial preparation process and sterilization ability, obtained hydrogels might have high potential for use in bone tissue engineering.

INTRODUCTION: The dermis is divided into distinct compartments, the superficial papillary dermis and the deeper reticular dermis, which display structural and functional differences especially in terms of vascularization and mechanical properties. Primary human fibroblasts isolated from these compartments differ in morphology, proliferation and patterns of gene expression. To date, we are still lacking models allowing investigation of their microenvironment and ability to support capillary formation, as well as insertion in reconstructed skin. The aim of this research work was thus to study and compare the properties of human papillary and reticular fibroblasts in tissue-engineered cell sheets.

METHODS: Endothelial cells were cultured in fibrin hydrogels in the presence of conditioned medium of human papillary and reticular fibroblasts in order to assess the angiogenic paracrine factors. Both fibroblast subpopulations were also co-cultured with endothelial cells on thermo-sensitive culture dishes under conditions that promote extracellular matrix deposition and support capillary formation. Angiogenic properties were measured, and RNA-seq was performed for gene expression analysis.

RESULTS & DISCUSSION: Using 3D angiogenesis assays based on conditioned medium, we could demonstrate that paracrine factors from papillary fibroblasts induce the formation of dense branched capillary networks. Using cell sheet angiogenesis assays, we could demonstrate that the microenvironment generated by reticular fibroblasts regulates vessel diameter and perivascular cell recruitment. The results from these functional assays were further supported by the identification of genes associated to vascular development and extracellular matrix.

CONCLUSIONS: Our results demonstrate that tissue-engineered cell sheets using subpopulations of dermis fibroblasts are important tools for identification of factors responsible for the specific microenvironment and vascularization of these dermis compartments. Furthermore, our data support the use of such culture technology for the generation of relevant micro-tissues mimicking the complex organization of the dermis.
Plant-derived cellulose hydrogel as a matrix for 3D human stem cell proliferation and differentiation
L. Paasonen¹, J. Spencer-Fry¹

¹UPM-Kymmene, Helsinki, Finland

INTRODUCTION: In the pursuit of in vitro cell models that are biological relevant with improved functionality, new materials and methods for creating three-dimensional (3D) cell culture systems are a key requirement. GrowDex®, nanofibrillar cellulose (NFC) hydrogel which is derived from the Birch tree, has been shown to provide an effective support matrix for culturing cells in 3D.

METHODS: 1) hESC (WA07) and hiPSC (iPS(IMR90)-4): Cell colonies were embedded in 0.5% GrowDex (UPM) in mTeSR1 (STEMCELL Technologies) media and cultured on 96-well plate up to 26 days. hPSCs pluripotency was analysed with OCT4 and SSEA-4 marker expression, in vitro EB-mediated differentiation, and teratoma assay. 2) hESC derived neuronal cells: Pre-differentiated neuronal cells were embedded in 1.5 and 1.0% GrowDex. Formation of the neuronal networks was evaluated by immunocytochemical staining against neuronal markers MAP-2 and β-Tubulin III and confocal microscopy. 3) Adipose tissue derived hMSCs: Cells were embedded in 0.2% GrowDex in DMEM media and transferred on 24-well tissue culture inserts. Adipogenic differentiation and osteogenic differentiation were induced with StemProTM differentiation kits (ThermoFisher) for 21 days, and analysed with Oil Red O and Alizarin Red S stainings.

RESULTS & DISCUSSION: 1) hESC and hiPSC proliferated in GrowDex without feeder cells, formed spheroids with 100-200 µm diameter (Fig.1A), and the cells remained their pluripotency throughout the 26 day study. 2) GrowDex supported the 3D growth of hESC derived neuronal cells. The formation of neurospheres and neuronal networks by neurite outgrowth were observed (Fig1B). 3) Adipose tissue derived hMSCs were able to differentiate to both adipogenic, and osteogenic direction in GrowDex 3D culture (Fig 1C,D).

CONCLUSIONS: GrowDex offers a well-defined, tunable 3D culture matrix for various regenerative medicine applications.

Figure 1: A) iPS(IMR90)-4 spheroids in 0.5% GrowDex. B) Neurite outgrowth from hESC derived neuronal cells in 1.0% GrowDex. C) Adipogenic differentiation and D) osteogenic differentiation of hMSCs in 0.2% GrowDex.

INTRODUCTION: Multiple sclerosis (MS) is one of the leading diseases causing non-traumatic neurological disability in the young adult. One of the treatment approaches is based on delivery of an API via the olfactory region in the nasal cavity. Here we describe development of hyaluronic acid-based hydrogel which can be crosslinked in the nasal cavity and serve as a mounting layer preventing clearance of API from the site of application. Hyaluronan-tyramine derivative (HA-TA)¹ is capable of forming hydrogel due to crosslinking by UV light in the presence of photoinitiator riboflavin (Rbf.).

METHODS: Influence of different parameters (HA-TA DS and Mw, Rbf. concentration, UV intensity) on precursor solution viscosity, gelation time and elastic modulus (G’) of hydrogel was evaluated by using rotational rheometer. HA-TA+Rbf. precursor solution cytotoxicity, hydrogel extract cytotoxicity and phototoxicity were tested. 3T3 cells (1,5·10⁴/ml/culture well) viability were measured with ATP assay.

RESULTS & DISCUSSION: The viscosity of HA-TA precursor solution is a crucial parameter for material applicability and its spreading in the targeted place of nasal cavity. Kinetics of gelation depends on photoinitiator concentration. Precursor solutions and hydrogel extracts are non-cytotoxic.

CONCLUSIONS: HA-TA hydrogel is possible to crosslinked in situ by UV light. It is non-cytotoxic, stable with tuneable hydrogel properties.

INTRODUCTION: Cartilage degeneration and synovitis are key hallmarks of joint degenerative diseases, such as osteoarthritis (OA). The communication between these two tissues is fundamental to maintain both homeostasis and disease onset. However, studying this communication has remained challenging. Herein, we propose a novel modular precision microfluidic platform, that combines a synovial membrane-on-chip and a cartilage-on-chip platform. This seamless strategy enables the facile and in depth study of cross-communication between these two joint components, specifically via inflammatory mediators, aiming to replicate the onset of OA.

METHODS: Two types of microfluidic PDMS-based chips were designed with actuation chambers to emulate the mechanical forces of the cartilage and synovial membrane. For the cartilage chip, human healthy and OA affected chondrocytes were seeded in an ECM-like hydrogel. The synovial membrane chip was composed of a hydrogel re-enforced by an elastic membrane, which was seeded with synovium fibroblasts. Both chips were connected by a common channel, where synovium mimicking medium (culture medium supplemented with HA) was flowing (60 µl/hr). After both tissues achieved phenotypical maturation, human macrophages were added to the system. The behavior of the immune cells were a key read-out, focusing on their mobility, cytokine and proteinase release profile (ELISA) and polarization ratio between M1 and M2 (qPCR). On-line and end-point analysis were conducted after 1, 3 and 7 days.

RESULTS & DISCUSSION: The unique chip actuator designs allowed for physiologically relevant stimulation of the cartilage and synovial membrane, by cyclic compression and stretching, respectively. The effect of the mechanical load was determined on the release of inflammatory mediators. The proteinases and inflammatory cytokine profiles are the basis of the fingerprint of the influence of the variables: static vs. mechanically stimulated, healthy vs. OA-affected chondrocytes, and, presence vs. absence of macrophages.

CONCLUSIONS: This modular joint-on-chip platform has the potential to provide unprecedented insights in the effects of inflammation of a single joint tissue, the performance of the various joint tissues, and the joint function itself.

INTRODUCTION: Decellularized tissues offers an excellent approach to study cell-ECM interaction in health and disease. In this study we have used peripheral lung tissue from healthy individuals and patients suffering from idiopathic pulmonary fibrosis (IPF). IPF is a devastating disease characterized by excessive matrix production and stiffening of the tissue. The aim was to examine temporal changes in the original ECM in healthy and diseased scaffolds and how these affect protein production of repopulating lung fibroblasts cultured using heavy isotope labelling (SILAC).

METHODS: Human lung tissue slices (350µm) were decellularized using CHAPS to generate biological scaffolds. The scaffolds were characterized by density, biomechanical properties, histology, and mass spectrometry (MS). Scaffolds were mounted on custom-made holders, to mimic the native setting, seeded with human primary fibroblasts derived from a healthy donor, and cultured using SILAC medium supplemented with ¹³C₆ labeled L-Arginine-HCl and ¹³C₆ ¹⁵N₂ -labeled L-Lysine-2HCl. The repopulated scaffolds were examined as described above to study differences in ECM turnover.

RESULTS & DISCUSSION: Heavy isotope labelling of the cultured cells allowed us to follow up- and downregulation of the newly synthesized proteins in compared to the original scaffold due to a mass shift detectable in MS. Interestingly, healthy fibroblasts cultured on IPF scaffolds had a protein production profile overlapping with the profile of the original scaffold.

CONCLUSIONS: We demonstrated that using SILAC in our biological system allowed us to study temporal differences in protein production in healthy and diseased scaffolds. Furthermore, by culturing under static stretch we created a 3D environment similar to the native situation, strongly influencing the cellular response. Collectively, this opens up for in depth identification of proteins involved in lung disease and tissue regeneration. Our goal is to identify a combination factors that can be used to locally trigger a healthy regeneration of the lung.

INTRODUCTION: Chronic obstructive pulmonary disease (COPD) is an increasing worldwide health problem characterized by progressive tissue destruction with no cure. In end-stage disease, the ultimate treatment is lung transplantation. Due to lack of compatible donor lungs and the problems with graft rejection, tissue engineering approaches have emerged as an alternative. Knowing that biomechanical loading is fundamental for the optimal cellular response, we have constructed a bioreactor mimicking the in vivo setting. The bioreactor makes it possible to study regeneration of human lung tissue.

METHODS: Lung scaffold slices 350 µm thick and with a surface area of 1 cm² were produced from both human and porcine tissue using a decellularisation protocol developed in our lab. To introduce static stretch to lung tissue-derived scaffolds, a custom-made scaffold holder was developed (Fig. 1). Scaffolds are placed over a base with an open hole, an O-ring is placed on top and a lid with an open hole secures the scaffolds. The construction of the bioreactor is based on the same principle. Here, scaffolds are mounted on top of an elastic membrane creating a pressurized chamber underneath. Movement of the membrane and the overlying tissue controlled by alternating the pressure. Human fetal lung fibroblasts (HFL-1) were cultured for up to 6 days on the porcine scaffolds. Subsequently, scaffolds were analyzed histologically and assessed for cell viability (resazurin-based assay).

RESULTS & DISCUSSION: In contrast to our previous studies, the tissue-derived lung scaffolds from healthy subjects retained its normal alveolar structure when cultured under static stretch compared to non-mounted scaffolds. In the latter, cells contracted the surface area from approx. 1 cm² to 2 mm² in 6 days. Cells seeded on scaffolds, cultured under cyclic dynamic loading in the bioreactor, have a higher viability and a more even distribution compared to cells cultured in static stretch. No differences in cell numbers were observed.

CONCLUSIONS: Creating a 3D environment mimicking the in vivo setting of the lung is crucial for the development of tissue engineering approaches in regenerative medicine. We have designed a bioreactor that can be commercialized, and used for studying regeneration of human tissue, as well as an alternative for animal testing in toxicology and/or pharmacology studies.

INTRODUCTION: To create a (fibro)cartilage construct, a modular strategy can be applied where high quality microtissues are used as building blocks [1]. In this study, 3D spheroids with a (fibro)cartilage phenotype are generated, using porcine articular chondrocytes (pAC) or human bone marrow-derived mesenchymal stem cells (hBM-MSC). For the directed assembly of these spheroids by 3D bioprinting, a modified photo-crosslinkable gelatin (Gel-MOD) was used as a bio-ink [2].

METHODS: Porcine AC were enzymatically isolated from the articular cartilage of the femur. hBM-MSC were purchased from PromoCell. To generate spheroids, a high-throughput agarose microwell system, with 1585 pores of 400 µm diameter, was used. After seeding 0.5 x 10⁶ cells per well, uniform spheroids of ± 315 cells were obtained and cultivated at 5% O₂ in chondrogenic medium. To assess the effect of the biopolymer concentration of the hydrogel on the spheroids, encapsulation experiments were performed. For the encapsulation in gelatin methacrylamide, spheroids were mixed in a 10, 15 or 20 w/v% Gel-MOD solution (PBM Group, UGent) with 2 mol% Irgacure 2959 or 20 mol% VA-086 as photo-initiator. Spheroids were bioprinted with a 3D Discovery Instrument (RegenHU). The viability, morphology and extracellular matrix (ECM) of the spheroids were evaluated by live/dead staining, (immuno)histochemistry and RT-qPCR.

RESULTS AND DISCUSSION: After 14 days of culture, compact and circular pAC or hBM-MSC spheroids were encapsulated in Gel-MOD. Encapsulated spheroids remained viable and were positively stained for GAGs, collagen I and collagen II. Hydrogel properties had an influence on spheroid phenotype. More importantly, using different biopolymer concentrations led to a shift of the spheroid phenotype to a more fibrocartilage or cartilage-like phenotype, demonstrating the impact of biopolymers on the cellular behavior.
(Fibro)cartilage spheroids combined with a 10 w/v% Gel-MOD solution with Irgacure 2959 as photo-initiator, were used to bioprint a larger construct. After printing, spheroid viability and ECM remained stable.

CONCLUSIONS: This study demonstrated that spheroids can be used as modular building blocks for the engineering of a larger-scale (fibro)cartilage construct. Furthermore, Gel-MOD is a suitable bio-ink for 3D bioprinting as it supports the viability and phenotype of the spheroids.

ACKNOWLEDGEMENTS: The authors would like to thank Liesbeth Tytgat, Prof. Dr. Sandra Van Vlierberghe, Prof. Dr. Peter Dubrue and the PBM Group (Faculty of Sciences, Ghent University) for kindly providing the Gel-MOD.

INTRODUCTION: The corneal endothelium is a hexagonal monolayer which plays a crucial function in the maintenance of the dehydration and transparency of cornea. Once corneal endothelial cells (CECs) are damaged or malfunctions, corneal edema and vision loss ensues. However, the CECs are terminally differentiated with barely regenerative capability and can lose by aging or injury. Therefore, the acquisition of proper and sufficient cell resource for CECs transplantation is extremely important in corneal regenerative medicine [1-2]. Herein, we explicate an applicable procedure to access differentiated CECs from human embryonic stem cells (hESCs) by using serum-free and feeder-free culture system.

METHODS: Human embryonic stem cells were seeded on Matrigel™ coated dishes in mTeSR™ medium for 5-6 days by changing medium daily. When the hESCs reached 60–70% confluence, the medium was changed to hESCs medium supplemented with B-27 (Invitrogen), PDGF-BB (PeproTech) and DKK-2 (PeproTech). Media were changed every other day. Immuno-cytochemistry, and real-time PCR analyses were conducted after 1, 2 or 4 weeks.

RESULTS & DISCUSSION: After differentiation of hESCs into CEC-like cells, the corneal endothelium marker N-cadherin, tight junctional protein ZO-1, functional pump protein sodium-potassium ATPase, and the main component of the corneal stroma collagenVIIIA1 were detectable. Real-time PCR analyses illustrated significant increase (p < 0.05) in AQP1 expression after CECs induction.

CONCLUSIONS: Through this study, we can obtain quantity of hCECs in hope of bringing these cells into tissue engineering and clinical use in the future.

INTRODUCTION: Liver fibrosis is accompanied by aberrant changes in the extracellular matrix (ECM) structure and composition that alter cell signaling when interacting with hepatic cells and invading inflammatory cells. Understanding the mechanisms of interaction between these elements in the context of liver injury is key to determine new therapeutic interventions, but current culture and animal models do not recapitulate the complexity of liver fibrosis. Here we used a tissue engineering approach to create a 3D-dynamic, humanized model of liver fibrosis incorporating the liver ECM, native hepatic cells and immune cells circulating in a custom-made perfusion bioreactor.

METHODS: Liver scaffolds were produced by decellularization of whole rat liver with established treatment [1]. Hepatic stellate cells (HSCs) were isolated from liver biopsies and peripheral blood mononuclear cells (PBMCs) from matched whole blood or from healthy controls. Decellularised scaffolds were perfused with either PBMCs or HSCs and cultured in static or dynamic conditions for up to 7 days. Scaffolds were analyzed by histology and immunofluorescence.

RESULTS & DISCUSSION: Whole livers were successfully decellularized to remove native cells and DNA, retaining ECM and vasculature. In both static and dynamic culture conditions, scaffolds supported PBMC viability and homing of immune cell subsets. Whole liver decellularized scaffolds perfused with PBMCs showed homing of CD68+ macrophages and CD3+ T cells. The custom-made bioreactor was able to support continuous perfusion of PBMCs and different shear stresses were tested on cell viability by modulating media viscosity and perfusion flow rate. Bioreactor-guided serial seeding of HSCs produced re-populated liver scaffolds where fibrosis was induced by adding TGFβ, activating αSMA expression in HSCs. Cells were also transfected to express the enzyme luciferase allowing non-invasive cell tracking in 3D cultures using bioluminescence imaging for daily quantification/localization analysis of cells.

CONCLUSIONS: These data support the use of decellularized whole liver scaffolds seeded with primary HSCs and perfusion of matched PBMCs in a custom-made bioreactor as an immune-competent 3D model of liver fibrosis.

INTRODUCTION: The reconstruction of large bone defects resulting from severe trauma or resection of tumors remains a challenge for orthopedic and plastic surgeons. Today, a vascularized bone (e.g. fibula, floating rib) is taken from the patient and grafted into the defect. However, this transplantation adds morbidity and requires extensive micro surgery to adapt to both the vasculature and the skeleton. We propose an alternative approach consisting of manufacturing patient specific biomaterial scaffolds through 3D printing. This study aims to demonstrate the feasibility of regenerating large bone defects with 3D printed anatomically accurate biomaterial scaffolds in sheep.

METHODS: The left posterior limb was scanned by computed tomography (CT, Siemens Somatom) and a contrast agent was injected in order to visualize the metatarsus and the vasculature. CT data were imported into medical imaging software and converted to STL files. The metatarsus bone of sheep was 3D printed with PLA filament (Ultimaker 2) from the CT scans. It allowed surgical planning with the placement of an osteosynthesis plate and screws. A cutting guide was also designed and 3D printed in order to create a segmental defect of 35 mm in the metatarsus. A specific biomaterial was produced by 3D printing using a calcium phosphate / pluronic paste that hardens into a porous scaffold. Three groups were considered: empty defects, and defects filled with either a customized biomaterial scaffold, or the biomaterial scaffold with a vascular pedicle running through it. After surgery, bone regeneration and vascularization were followed by CT at 30, 60 and 90 days. Sheep were euthanized and a vasculature contrast agent (Microfil) was injected into the femoral artery. Metatarsus were dissected, fixed in formadehyde 4%, analysed by microCT (Skyscan 1076) and embedded in PMMA for non-decalcified histology.

RESULTS & DISCUSSION: The biomaterial scaffold was made of calcium phosphate apatite with similar composition as bone mineral. Its shape perfectly fitted the metatarsus bone defect. The scaffold had interconnected porosity to favor bone regeneration. CT scans indicated that the empty defect remained non-bridged after 3 months. A limited bone healing was observed with the 3D scaffold. The vascular pedicle going through the scaffold was functional without thrombosis. The vasculature favored bone regeneration of the critical size metatarsus defect. Numerous capillaries were observed inside the 3D scaffold by microCT and histology.

CONCLUSIONS: This pre-clinical study demonstrated the feasibility of 3D printing patient specific biomaterial scaffolds for regeneration of large bone defects resulting from severe trauma or resection of tumor.

INTRODUCTION: 3D bioprinting is an emerging technology which involves additional complexities compared to additive manufacturing, known as three-dimensional (3D) printing, such as hydrogels, cells and growth factors for tissue engineering. 3D bioprinting is ideal for translational medicine and also for basic research applications as it allows tissue engineering based on patient-specific designs. During the bioprinting process, hydrogels are used for printing cells in order to create 3D tissue constructs. This hydrogel, also called bioink, must possess appropriate mechanical, biological and rheological properties for maintaining its shape during cell culture and for allowing cell proliferation and functionality for the tissue development. 3D bioprinting is also an excellent technology for studying drugs and cells interactions in 3D human tissue constructs at the pre-clinical level.

METHODS: In our study, we have developed an innovative bioink, combining gelatin, alginate and fibrinogen (GAF) hydrogels for 3D bioprinting and culturing human mesenchymal stem cells (hMSC). Spherical Hydroxylapatite particles were also loaded in GAF hydrogels containing hMSC and successfully bio-printed into 3D constructs for bone tissue engineering. The rheology of this bioink was first studied in order to optimize the best printability and stability in culture medium as function of composition.

RESULTS & DISCUSSION: Cell viability and proliferation of human mesenchymal stem cells in 3D bioprinted GAF scaffolds were investigated by using fluorescence microscopy and Alamar Blue assay. Results demonstrated a good cell adhesion, spreading and proliferation of hMSC in the GAF-HA bioink.

CONCLUSIONS: In summary, this study showed that this innovative bioink is suitable for bone tissue engineering. This 3D model may be useful for studying bone metastasis behavior of different kinds of cancers like breast and prostate tumors as well as for drugs interactions (ex: chemotherapy).

INTRODUCTION: Worldwide, a large number of surgical procedures to replace or repair tissues damaged by disease or trauma are performed every day. For this purpose, decellularized extracellular matrix (ECM) derived from native human tissues has been recently considered for clinical use and been extensively studied. The advantages of ECM include their full biocompatibility and biodegradability. Importantly, this material contains endogenous bioactive molecules such as cell adhesion proteins, growth factors etc. that support cell adhesion, growth and proper function leading to production and growth of the new tissue.

In this study, we focus on development of biomaterials composed of isolated human bone ECM. Within the study, materials based on inorganic (bioapatite) and organic parts of human bone ECM is developed. The isolated bioapatite is developed as an additive with osteoinductive and osteoconductive properties for enhancement of biological properties of other commonly used materials in clinical practice. The demineralized bone matrix is developed also as an additive (same as the bioapatite) or in the form of a hydrogel scaffold for cell incorporation.

Data obtained from evaluation of their osteoconductive and osteoinductive potential will be presented at the conference.

METHODS: A sample of human bioapatite was isolated from chemically and thermally treated human femoral head. Briefly - bone was cut into slices and treated by 2% NaCl solution at 150°C and 0.2 MPa in an autoclave, followed by degreasing in an acetone-ether mixture for 24 hours and by treatment with 4% NaOH solution at 70°C for 24 hours. The chemically treated bone was calcined overnight at 500°C under atmospheric pressure and dried at 105°C. Organic part was obtained by demineralization of human femoral head by 0,6M HCl for 48 hours followed by neutralization and lyophilization.

ACKNOWLEDGEMENTS: Financial support was received from Czech Ministry of Industry and Trade (CZ.01.1.02/0.0/0.0/17_107/0012524).

INTRODUCTION: Cardiac tissue engineering is envisioned as a regenerative therapy to treat myocardial infarction (MI). In this approach cardiac cells are seeded within three-dimensional (3D) porous scaffolds to create functional cardiac patches. AuNRs are well-known for their biocompatibility and chemical inertness. Recently, it has been shown that gold nanostructures, such as spheres or particles can be incorporated into 3D scaffolds to increase the transfer of the electrical signal between electrogenic cells. In addition, it has been demonstrated that AuNRs are able to significantly increase the conductivity of natural materials without affecting the relevant mechanical properties for cardiac tissue engineering. We sought to utilize these properties to improve the electroactive properties of a chondroitin sulfate hydrogel and develop 3D scaffolds for tissue engineering with an efficient control release system.

METHODS: Chondroitin sulfate (CS) hydrogel was fabricated by dissolving in NaOH and crosslinking with ethylene glycol diglycidyl ether (EGDGE). In order to integrate the AuNRs within the hydrogel, a concentrated solution was added on the last step of gel formation. Using electrical stimulation we released stromal-cell derived factor 1 (SDF-1), which was evaluated by ELISA. To assess the effect of release cell migration towards the released factor was evaluated using a chemotaxis chamber.

RESULTS & DISCUSSION: We have integrated AuNRs in to the CS hydrogel (Figure 1). We have shown that SDF-1 could be released into the scaffold's microenvironment in a voltage-dependent manner. Alternating the electrical stimulation showed a significantly higher release of the protein from the Au-modified CS hydrogel (Figure 2). Moreover, the release was translated into higher number of migrating cells within the modified scaffolds (Figure 3).

CONCLUSIONS: We have shown that the protein could be released into the scaffold's microenvironment in a voltage-dependent manner. The results indicate a high release of SDF-1 from CS with high concentration of AuNRs. This suggests that integrating the particles into 3D electroactive CS hydrogel improved the local electrical conductivity of the hydrogel.

Figure 1: (1) TEM micrographs of a CS-AuNRs composite system. (2) An On–off controlled release profile of SDF-1 from the scaffolds. (3) Cell migration as a result of SDF-1 release.
Alginate/agarose scaffolds induce gene expression of cartilage-related genes in vitro

INTRODUCTION: Hydrogels, used in tissue engineering to stimulate the poor ability of cartilage to regenerate, have demonstrated good chondrogenic properties. We reported that alginate/agarose hydrogels generated a chondrocyte-friendly environment in vivo and in vitro [1], inducing chondrocyte primary cultures and human dental pulp mesenchymal stem cells (hDPSCs) to differentiate into chondrocytes, that presented type II collagen and aggrecan. Our main objective was to characterize at the molecular level the expression of different genes in order to explore if both cell types grown in these scaffolds differentiate to a stable or to a hypertrophic chondrocyte phenotype.

METHODS: Low-melting fusion point agarose (1%) was mixed with alginate (3%) and polymerized together. Human primary articular chondrocytes and hDPSCs were isolated and cultured in the 3-D agarose/alginate scaffolds with chondral proliferation or differentiation media [1] for up to 6 weeks. Chondrocytes differentiation markers (type I and II collagens and aggrecan) were studied by immuno-fluorescence. Morphology changes were evaluated by fluorescence microscopy using rhodamine-phalloidin. Total RNA was extracted and real time RT-PCR was used in order to analyze the expression of extracellular matrix (COL1A, COL2A1, ACAN), SOX (SOX5, SOX6, SOX9) and RUNX (RUNX9, COL10A1, MMP1, MMP3 and MMP13) related genes.

RESULTS & DISCUSSION: Cells grown in alginate/agarose scaffolds developed a chondral-compatible phenotype, with a high presence of type II collagen and aggrecan when differentiation medium was used. They became rounded and formed spheroids, with no stress fibbers observed. Concerning gene expression, the relative expression levels of COL2A1 and ACAN increased, whereas SOX5, SOX6 and SOX9 were significantly upregulated in both cell types. No increase of COL10A but a decrease of COL1A was observed. Nevertheless, a significant increase of the expression levels of MMP13 was found.

CONCLUSIONS: Cells grown in these scaffolds developed a round shape, formed spheroids and expressed high levels of COL2A1 and ACAN, observed by immunofluorescence and real time RT-PCR. The high increase of SOX gene levels, together with a decreased of COL1A1 indicate a stable chondral phenotype, which was enforced by the poor levels of COL10A1, associated to hypertrophic chondrocyte. Nevertheless, the increase of the expression of MMP13 could be indicative of a hypertrophic phenotype development, therefore more studies are necessary in order to clarify this question.

INTRODUCTION: Functionalization of the polymeric membranes through the incorporation of bioactive components may create a specific chemical context, enhancing their osteoconductive properties [1]. The aim of this study was to evaluate the bone-regeneration efficiency of novel polymeric nanostructured membranes and the effect of zinc, calcium, titanium and bone morpho-protein (BMP) loading of the membranes, through in vivo rabbit model.

METHODS: Nanostructurated membranes of methyl-methacrylate were loaded with zinc, calcium, TiO₂ nanoparticles and a recombinant bone-morphogenetic protein (BMP-2). A fifth group of unloaded membrane was tested. These membranes covered the bone defects prepared on the skulls of six rabbits. A sixth bone defect was uncovered (control). Animals were sacrificed six weeks after surgery. Micro computed tomography (µ-CT) was used to evaluate bone architecture trough BoneJ plugging and ImageJ script. Three histological processing of samples, including von Kossa (VK) silver nitrate, toluidine blue (TB) and fluorescence by the deposition of calcein were utilized.

RESULTS & DISCUSSION: Zn-Ms (M-Zn) promoted the highest amount of new bone and higher bone perimeter than both unloaded and Ti-Ms (M-Ti). Ca-Ms (M-Ca) promoted higher osteoid perimeter and bone perimeter than Zn. The skeleton analysis showed that Zn promoted higher branches and junctions of the trabecular bone than BMP-loaded membranes (M-BMP). Euler characteristics and spatial connectivity were higher in samples treated with Zn and BMP, when compared with the control group (CG). Samples treated with Ti showed less bone formation and bony bridging processes. Both Zn and Ca promoted higher number of osteoblasts than CG. BMP and Ca originated higher number of blood vessels than Ti and CG.

CONCLUSIONS: Almost complete union was observed throughout the defects treated with M-Zn showing zones which were occupied by bone-like structures, suggesting that substantial level of new bone was formed in the defect area [2]. In other groups (M-Ti and M-unloaded) the center of the defect was still radiolucent which suggests less bone formation. New bone appeared at both sides of the membrane after using Zn and Ca. M-Ca showed small trabeculae and maximum branch length but low osteogenic potential and scarce angiogenesis [3] than M-Zn. It may be concluded that Zn provided higher regenerative efficiency for bone healing at the created calvarian defects.

INTRODUCTION: The harvesting of adherent cells can be carried out by two ways: enzymatically or mechanically. Both procedures can reduce the cell viability, while are difficult to scale up. Although alternative systems have appeared with the temptation of replace the current methods, very little efforts have been exerted employing biosynthetic polymers, such as elastin-like recombinamers (ELRs). Herein has been exploited the versatility of ELRs. Different modules and bioactive sequences can be added, making ELRs promising building blocks for stimuli-responsive materials1. On the other hand, the poly(methyl methacrylate) (PMMA) has been widely used in medical applications due to its versatility and biocompatibility, making it a very interesting option as substrate beneath the ELRs.

METHODS: ELRs were obtained by genetic engineering techniques and produced in E. coli. All ELR sequences contain lysine residues in order to graft them covalently onto the surfaces through the amine groups. Including the integrin-recognized RGD2 sequence, cell adherence is conferred to the recombinamers. The functionalization of the biomolecules was performed following a three-step protocol.

RESULTS & DISCUSSION: The biosynthesized ELRs were characterized by: SDS-PAGE, MALDI-TOF, NMR, FITR-ATR, and DSC. The PMMA control and the resulting coated surfaces were characterized by water contact angle XPS, ESEM and AFM. Studies of adhesion, proliferation and harvesting were accomplished employing HFF-1 cells (figure 1).

CONCLUSIONS: The previous mentioned disadvantages can be overcome by employing surfaces coated by a temperature-responsive bioactive polypeptides showing stimuli-dependent cell adhesion. The values of transition temperature of ELRs were in the range 24.2–32.2°C, indicating that all the recombinamers would be folded at 37°C and unfolded at temperatures below 15°C. The contact angle measurements showed the temperature-responsiveness of the surfaces at different temperatures. Studies of adhesion and proliferation accomplished confirmed the efficacy of the cell harvesting.

INTRODUCTION: The coating of cell culture substrates with thermoresponsive polymers provides a valuable technique in the field of tissue engineering. In conventional cell harvesting, proteases are employed which degrade the endogenously produced extracellular matrix of cells and cell-cell junctions. In contrast, thermoresponsive coatings allow a gentle harvest of single cells and confluent cell sheets by switching from a less hydrated, cell-adhesive state to a more hydrated, cell-repellent state by simply reducing the temperature (Figure 1). In this work, we focused on the generation of renal and vascular cell sheets to develop an advanced model for studying drug transport and toxicity in the kidney. We hypothesize, that dynamic culture conditions influence the thermoresponsive cell sheet harvest by induction of tight junction formation.

METHODS: We established functional thermoresponsive polyglycidyl ether (PGE) coatings for the detachment of human renal proximal tubule epithelial cells (RPTEC) and human umbilical vein endothelial cells (HUVEC) as mono- and bilayers. Detachment characteristics and functionality of the cell sheets were analysed. Cells were also cultured in a bioreactor system to investigate the impact of flow conditions (time and shear rate) on cell orientation and cell sheet detachment (Figure 2).

RESULTS & DISCUSSION: The PGE coatings permitted the successful detachment of epithelial and endothelial cells. The functionality of the cell sheets regarding polarisation, expression of transport proteins and barrier integrity was demonstrated. Preliminary experiments revealed that the application of shear stress under dynamic cultivation conditions influences the detachment of cell sheets.

CONCLUSIONS: We were able to harvest intact and functional sheets of different cell types via thermoresponsive PGE-coatings. In perspective, the combination of these cell sheets with 3D-printed scaffolds will allow the establishment of an advanced 3D-model of the proximal tubule for further dynamic maturation and evaluation of drug transport and toxicity.

INTRODUCTION: Surgical procedures are nowadays a current practice in dentistry not only for oral rehabilitation (implants) but also for guiding periodontal regeneration. These practices often require the use of membranes to stimulate tissue regeneration, mostly based on natural polymers, such as collagen (COL). Periodontitis is a common disease of the gums that may develop with severe consequences if an appropriate solution is not timely implemented. Under a weak immune response of the patient periodontitis may progress to periodontal bacteria, allowing infection to propagate from the gum to the roots of the teeth, with serious damages including the destruction of periodontal ligament and the supporting bone and ultimately the loss of teeth [1]. The objective of the present work is to develop composite collagen membranes filled with nanohydroxyapatite to be used in oral rehabilitation and periodontal regeneration.

METHODS: Hydroxyapatite nanoparticles, as fillers, were synthesized by chemical precipitation. COL-based composite membranes were produced by two different techniques including (i) freeze drying and (ii) freeze drying followed by uniaxial pressing under controlled conditions. The produced materials were fully characterized by XRD, SEM/TEM, zeta potential, gas adsorption and FTIR spectroscopy. The in vitro bioactivity of the produced membranes were accessed by immersion tests in synthetic plasma. The degradation profile of the membranes was also examined in PBS.

RESULTS & DISCUSSION: The composite membranes exhibited a bioactive behavior suggesting its potential for application in dental tissue regeneration. Furthermore, the degradation rate of the membranes is affected by the technique used for the membrane manufacturing, being higher for the uniaxially pressed membranes.

CONCLUSIONS: The developed COL-hydroxyapatite composites are an interesting alternative to the current barrier periodontal membranes. The performance of the membrane in terms of in vitro surface activity and/or degradation may be triggered by an appropriate selection of the fabrication details.

INTRODUCTION: The success of tissue engineering (TE) is based on the choice of the 3D matrix to support the adhesion, proliferation and differentiation of cells. The chemical composition, the physical and mechanical properties, the biodegradability, biocompatibility, and functionality of the 3D scaffolds are crucial characteristics for their use in TE applications [1]. Direct Laser Writing (DLW) is a powerful technique for the fabrication of 3D structures, via a computer-aided design (CAD), for use in optics, metamaterials as well as in the field of biomedical applications [2]. In this study, we have synthesized gelatin methacrylamide (GelMA) and a water-soluble chitosan derivative (chitosan-mod). Hybrid materials of these two biopolymers were employed to fabricate 3D scaffolds via DLW and their ability to support cell growth and mineral matrix was investigated in cell culture.

METHODS: Near IR laser irradiation, operated at 800 nm, was employed to fabricate the 3D scaffolds, in the presence of eosin-Y, as a water soluble, FDA-approved photoinitiator and without any other co-initiators or co-monomers [3]. Cell behavior on the hybrid materials (2D films and 3D scaffolds) was examined using dental pulp stem cells, generously donated by Prof. Athina Bakopoulou, School of Dentistry, Aristotle University of Thessaloniki. Cell adhesion on the 3D scaffolds was visualized by immunocytochemical staining of the actin of the cytoskeleton and the cell nuclei as well as by scanning electron microscopy (SEM). In addition, the 3D scaffolds were functionalized with physically adsorbed BMP-2 and cultured for 21 days.

RESULTS & DISCUSSION: Grid-shaped porous scaffolds with pore size of 70 μm and dimensions 400x400x37 μm³ were fabricated. We suggest that the free amine groups of GelMA and the chitosan derivative act as co-initiating moieties and support the photopolymerization process. We carried out the cytocompatibility investigations on geometrically well-defined films in order to quantify the cell proliferation results. For the hybrid material we observed a strong initial cell adhesion and a subsequent cell proliferation increase. The results indicate the absence of any cytotoxic effects and suggest that the biopolymer-based hybrid material is biocompatible and exhibits better biocompatibility than the TCPS control. Both immunocytochemistry and SEM characterization showed a strong cell attachment and an increased proliferation over time within the 3D porous scaffolds. The cells cultured for 21 days on the hybrid scaffolds demonstrate an enhanced mineral matrix compared to the control, and this effect is significantly higher on BMP-2 functionalized hybrid structures, as observed by the alizarin red staining.

INTRODUCTION: The Direct Laser Writing (DLW) technique is based on the localized polymerization/cross-linking of photosensitive materials, induced by femtosecond laser pulses, and has attracted great interest for the fabrication of 3D scaffolds for use in the fields of tissue engineering and regenerative medicine [1]. In this work, we present the development of a novel photosensitive, hybrid organic-inorganic material which combines excellent cell biocompatibility, calcium matrix deposition, and antibacterial properties conferred by a thymol methacrylate (TM) derivative as a natural antimicrobial agent [2].

METHODS: The material underwent a sol-gel process followed by two-photon polymerization (2PP) to fabricate complex 3D structures of high resolution. The cell viability and proliferation on photopolymerized thin films as well as 3D scaffolds, fabricated by 2PP, were examined by human dental pulp stem cell cultures, generously donated by Prof. Athina Bakopoulou, School of Dentistry, Aristotle University of Thessaloniki. In the current study two controls were used, tissue culture treated polystyrene (TCPS) and the hybrid material without the TM moieties. Cell adhesion on the 3D scaffolds was visualized by immunocytochemical staining of cytoskeleton actin and cell nuclei as well as by scanning electron microscopy (SEM). In addition, 3D scaffolds were further functionalized with bone morphogenetic protein 2 (BMP-2) via physical adsorption and cultured for 21 days [3]. Moreover, the antimicrobial action of the 3D scaffolds was evaluated against E. coli.

RESULTS & DISCUSSION: Grid-shaped porous scaffolds with pore size of 80 μm and dimensions of 555x555x50 μm³ were fabricated. The cells adhered strongly onto the material surfaces, similarly to the TCPS control. On days 2, 4 and 7 post-seeding, cell viability and proliferation increased. Both immunocytochemistry and SEM characterization showed a strong cell attachment and proliferation within the 3D porous scaffold of both hybrid materials. A large number of cells attached on the 3D scaffolds and attained their characteristic spindle-shaped morphology. The release of physically adsorbed BMP-2 from the scaffolds significantly increased the calcium mineralization deposits onto the 2PP structures after 21 days compared to the controls without BMP-2. Following the biocompatibility testing of the TM-functionalized hybrid material, we examined the antibacterial action of the 3D scaffolds. E. coli were cultured on the scaffolds for 1, 2, 3 and 4 days. The results showed that the bacteria can grow on the 3D scaffolds of the hybrid material that did not contain TM, while a dramatic reduction in the number of attached bacteria on the TM functionalized scaffolds was observed, which underlines the potency of the TM functionalized material for use in the development of biocompatible and antimicrobial 3D scaffolds that support mineralized tissue formation.

INTRODUCTION: Photo-sensitive drug delivery systems have attracted significant attention over the last decades. Near Infrared (NIR) light is a powerful tool for triggering drug release from nanocarriers because it offers deep tissue penetration without damaging the healthy ones. However, the majority of NIR-sensitive nanocarriers include the incorporation of upconverting nanoparticles or two-photon absorption processes [1]. Herein, we present for the first time a novel NIR-photoactivated chemically amplified drug release system by combining acid-degradable nanocarriers based on PEG-b-polyacetal block copolymer micelles with a photosensitization system comprising a photo-acid generator (PAG) that absorbs in the UV region and a photosensitizing molecule that absorbs in the NIR. The degradation of the nanocarriers is based on the acid-catalyzed cleavage of the acetal bonds along the main chain of the polyacetal block. The acid molecules are generated via an electron transfer process from the exited photosensitizer molecules to the PAG molecules, both loaded within the core of the block copolymer micelles.

METHODS: The PEG-b-polyacetal copolymers were synthesized via a two-step acid catalyzed polycondensation reaction between 1,4-benzenedimethanol and divinyl ether (first step) and end-capping of the precursor polymer with monohydroxy terminated poly(ethylene glycol) at the vinyl ends (second step) to afford the final block copolymer. Spherical micelles loaded with PAG/photosensitizer were prepared in water. The release of the cargo, following irradiation at 440 nm, 510 nm and 808 nm, was monitored by measuring the absorption of the released photosensitizer molecules as a function of irradiation time.

RESULTS & DISCUSSION: The proposed photoactivation mechanism was verified for three different irradiation wavelengths which correspond to the absorption maxima of the different photosensitizer molecules. In each case, the photosensitizers were chosen to have appropriate HOMO-LUMO energy states in order to achieve an effective electron transfer process. An increase in the degradation rate of the micelles and the release of the cargo was observed when increasing the PAG/photosensitizer mole ratio within the micellar core. Both the PEG-b-polyacetal micelles and the small molecule degradation products are non-toxic, hydrophilic molecules which can be effectively removed from the human body without causing side toxicity.

CONCLUSIONS: In conclusion, we introduce herein a novel NIR-activated system based on polyacetal nanocarriers and organic photosensitizers. Our novel system operates at 808 nm and very low irradiation energies which opens new pathways in the development of photo-activated drug delivery.

INTRODUCTION: Articular cartilage has a limited ability to repair itself, therefore, it is common to find pathologies related to cartilage injuries. In previous studies, where scaffolds/cell-free implants were used in an in-vivo experimental model in rabbits, hyaline cartilage is regenerated the upper part of the scaffold three month after the scaffold implantation [1,2]. This suggests that the rapid growth of the superficial layer of the cartilage covers the scaffold and the mechanical conditions due to the presence of the scaffold displaces it to the subchondral bone [1]. Given the above, our interest is to propose and develop a simulation tool to predict the results of polycrylate polymer implants, their weaknesses and advantages. In this way, to achieve a deeper understanding of the processes involved in the regeneration of articular cartilage.

METHODS: A computational simulation was developed, using finite element methods. The geometry of the cartilage, implant, subchondral compact and trabecular bones were considered (Figure 1). The subchondral compact bone, the trabecular bone, and the implant were modeled as poroelastic materials [3], whereas the cartilage was modeled as a poroelastic, fibril reinforced material [4]. Additionally, for the bone, a remodeling model was applied, so that its Young’s modulus changed according to the deformation [5]. Moreover, a model for bone and cartilage regeneration was included.

RESULTS & DISCUSSION: It is noticeable that the abnormal mechanical conditions that both bones, subchondral and trabecular, goes under might generate a bone remodeling process under the implant. Meanwhile, the implant gives support to the surrounding cartilage tissue. Also, as the bone under the implant remodels, it allows the implant to move downwards inside the bone. Moreover, as the implant displaces inside the bone, the cartilage tissue experiments ideal conditions to regenerate.

CONCLUSIONS: Computational simulation is suitable to explain the phenomenon of the articular cartilage regeneration. The obtained results are comparable to those observed in the experimental studies.

INTRODUCTION: Magnetic fields are applied in patients with articular chondral lesions in order to improve cartilage regeneration, but little is known about its direct effect on chondrocyte survival or morphology. In the present study we used chondrocyte cultures differentiated from human dental pulp mesenchymal stem cells (hDPSCs), and exposed them to a controlled magnetic field that reproduce mechanical forces by acting on cells, which could improve articular cartilage regeneration.

METHODS: hDPSCs (Lonza) were centrifuged into 0.5 ml microtubes to obtain 3-D pellets, and cultured with chondral proliferation medium (αMEM with 10% FBS, 1% L-glutamine and antibiotics). Samples were randomly assigned to 3 different groups. Treated cells (group A) were exposed on a daily schedule of 2 cycles (20 min irradiation, 40 min resting) x2, with 90 min resting time between each cycle, for 3 days, by means of a bioreactor [1] that originates a magnetic field (30 T/m, pulse direction changing every 3 s). Control non-irradiated samples were kept outside the cell incubator at RT (group B) in parallel to group A, or were maintained inside the cell incubator (group C). After the 3-day treatment period, viability assay (MTS) was carried out, cell morphology was studied by Harris hematoxylin-eosin staining, and chondral markers (type II collagen and aggrecan) were assessed by immuno-fluorescence, as well as actin content.

RESULTS & DISCUSSION: MTS viability test showed that irradiated cells (group A) presented an increased absorbance values with respect to control groups B and C. Cellular morphology were similar in all three groups, with cells showing a polygonal morphology with a spherical nucleus, and eventually small vacuoles in the cytoplasm, with similar actin content and distribution. Type II collagen was not observed in any group at this time of culture, whereas aggrecan was first observed in irradiated samples.

CONCLUSIONS: We have previously characterized the proliferation of hDPSCs and their ability to differentiate in chondrocytes [2]. We observe now that 3-day magnetic irradiation does not damage cell survival, on the contrary, an increase in cell viability was observed with respect to controls, as well as signs of early chondral differentiation (presence of aggrecan), suggesting it induces cellular proliferation and differentiation without altering cellular morphology.

INTRODUCTION: Nanotherapeutic strategies based in nanoparticles for local delivery of drugs, growth factors and other bioactive molecules inside the bone cells represent a significant advance in bone tissue engineering therapies [1]. Our recent studies evidence that ipriflavone-loaded mesoporous nanospheres induce a significant decrease of osteoclast proliferation and resorption activity after 7 days in coculture with osteoblasts, favouring the macrophage M2 reparative phenotype [2]. In the present study, the incorporation and effects of these nanospheres on undifferentiated MC3T3 -E1 preosteoblasts, the most common model of in vitro osteogenesis [3], have been evaluated through specific cell parameters and key differentiation markers.

METHODS: Hollow mesoporous SiO2-CaO nanospheres were labelled with fluorescein isothiocyanate (FITC-NanoMBGs) and loaded with ipriflavone (NanoMBG-IPs) as described previously [2]. MC3T3-E1 preosteoblasts were cultured in the presence of different doses of these nanospheres (10, 30 and 50ug/ml) in Dulbecco’s Modified Eagle’s Medium with 10% fetal bovine serum, 50 ug/ml -glycerolphosphate, 10 mM L-ascorbic acid, 1 mM L-glutamine, penicillin and streptomycin. FITC-NanoMBG incorporation by preosteoblasts was evaluated by flow cytometry and confocal microscopy. Cell viability, cell cycle phases, apoptosis, intracellular reactive oxygen species (ROS) and calcium were evaluated by flow cytometry. Alkaline phosphatase (ALP) activity and matrix mineralization were studied as key differentiation markers. Interleukin 6 (IL-6) secretion was quantified by ELISA.

RESULTS & DISCUSSION: FITC-NanoMBGs were incorporated by MC3T3-E1 preosteoblasts in a dose and time dependent manner. NanoMBG-IPs induced a significant increase of S cell cycle phase without inducing apoptosis. Intracellular ROS and calcium content decreased significantly after treatment with 50 μg/ml of NanoMBG-IPs 24 hours. No significant changes of IL-6 secretion were detected. Significant increases of both ALP activity and matrix mineralization were observed after 11 days of treatment with 50 μg/ml of NanoMBG-IPs, thus indicating their positive effects on in vitro osteogenesis.

CONCLUSIONS: These results ensure the potential application of ipriflavone-loaded mesoporous nanospheres as intracellular drug delivery system for bone regeneration by promoting osteogenesis.

INTRODUCTION: The Direct Laser Writing (DLW) technique is based on the localized polymerization/cross-linking of photosensitive materials induced by femtosecond laser pulses. An essential component of the photosensitive system is the photoinitiator (PI), required to initiate the polymerization/cross-linking process by multi-photon adsorption [1]. While, a large number of organic molecules, possessing high multi-photon absorption cross-sections (σ2), have been employed as PIs, the vast majority of them suffer from poor solubility in the solvent medium combined with a low yield of radical generation. Furthermore, many of the PIs are toxic and highly fluorescent, which limit their use in biomedical applications. To overcome these challenges, highly soluble, biocompatible and low-fluorescent molecules are essential for use as PIs in this field [2]. In the present study, we report the use of novel PI molecules for multi-photon polymerization.

METHODS: The photophysical properties of the PIs were investigated by UV−Vis spectroscopy. Two beam initiation threshold (2-BIT) was employed in order to determine the order of the effective nonlinear absorption of the new PIs. In addition, 3D structures were fabricated at different laser intensities and writing velocities. Finally, the biocompatibility of the PIs was assessed by investigating the adhesion, viability, and proliferation of human dental pulp stem cells on photopolymerized thin films containing 1 mol% of the employed PIs and comparing them to tissue culture treated polystyrene (TCPS) control surfaces.

RESULTS & DISCUSSION: All the PIs investigated in this study possess an absorption peak at around 370 nm and therefore, are expected to exhibit a two-photon absorption at around 800 nm. In addition, the PIs are transparent at 800 nm and have low fluorescence. Via the 2-BIT measurements the non linear order of absorption was found at around two, suggesting that these PIs have two-photon absorption at 800 nm. The polymerization threshold in all cases was lower than 3 mW, while the polymerization window was higher than 35 mW. The combination of low energy and high speed of polymerization resulted in the fabrication of 3D structures with high resolution (130 nm). Finally, we demonstrated the biocompatibility of the PIs by visualizing the cell morphology of the adhered cells onto the PI thin films, which is the same as on control TCPS surfaces. The cells show a very strong adhesion from the first day in culture and proliferate increasingly up to day 7 in culture. The viability of human dental pulp stem cells cultured on photopolymerized thin films containing 1 mol% of each PI indicate 70-80% of the cell viability on the TCPS control surface on day 1, and 90-100% on days 3 and 7 in culture.

INTRODUCTION: Antimicrobial surfaces that prevent biofouling from any type of microorganism are attractive in inhibiting the spread of microbial infections. Antibacterial surfaces are continuously being developed for a plethora of applications spanning from biomedical tools, packaging, marine technology and navigation.

METHODS: The primary amine groups along the main chain of chitosan were transformed into biocidal, cationic quaternary ammonium salt moieties upon reaction with alkyl halides. The degree of quaternization of chitosan was determined by proton nuclear magnetic resonance spectroscopy. Furthermore, this modification reaction enhanced the solubility of chitosan in water. Modified chitosan and an acid-labile acetal-based bifunctional alkyl halide, to act as a cross-linker of the polymer, were deposited and reacted on glass and silicon substrates. The thickness, wettability and morphology of the polymer films were assessed by ellipsometry, water contact angle measurements and scanning electron microscopy, respectively.

RESULTS & DISCUSSION: In this work, we have developed novel, biodegradable polymeric coatings based on modified chitosan bearing environmentally and toxicologically friendly biocidal groups. These coatings are able to self-polish and regenerate their antimicrobial activity upon repetitive bacterial fouling. The antimicrobial action of the polymer films was evaluated using two representative gram-positive and gram-negative bacteria strains. The controlled self-polishing behavior and the regeneration of the antimicrobial activity of the polymer films were investigated.

CONCLUSIONS: Chitosan was modified by reaction with alkyl halides to introduce cationic, biocidal groups along the polymer chain. The modified chitosan films were cross-linked using an acid-degradable acetal-based cross-linker. The antimicrobial activity of the cross-linked chitosan thin films was tested against both Gram-positive and Gram-negative bacteria and their self-polishing behavior was monitored in aqueous media by ellipsometry.

ACKNOWLEDGEMENTS: The project "Novel hybrid biocidal surfaces with self-renewal properties and direct detection of their antimicrobial activity" is implemented through the Operational Program "Human Resources Development, Education and Lifelong Learning" and is co-financed by the European Union (European Social Fund) and Greek national funds.
**INTRODUCTION:** Clinical tissue adhesives are important surgical tools, but currently available products have either weak cohesive bonding forces (e.g. fibrin-based glues) or harmful side effects of toxic components (e.g. cyanoacrylate-based glues). This leads to the need to develop new, biocompatible and strong bonding tissue glues. Ixodid ticks (Arachnida) produce a secretion, the cement, that bonds to tissue naturally. When the animals stitch their mouthparts into the host skin, they produce the cement to support anchoring during blood feeding. Since this adhesive has the potential to bond to humid and even wet tissue and is further suggested to be biocompatible, the material is of interest for medical glue research.

**METHODS:** Tick cement was harvested from adult Dermacentor marginatus that were fed in artificial feeding units on cattle blood. The material was macroscopically documented with high-resolution light microscopy, the adhesiveness tested with a surface force apparatus (SFA) and biomechanical properties measured with atomic force microscopy (AFM). Oil red staining was performed to detect lipids. For paraffin histology samples were fixed in paraformaldehyde and sections were stained with Arnow staining for catecholes, Biebrich Scarlet (BBS) for basic proteins, Periodic Acid Schiff (PAS) for carbohydrates and Alcian blue for acid muco-polysaccharides. For ultrastructural investigations samples were fixed with OsO4, resin embedded, sectioned and observed in a transmission electron microscope (TEM). Scanning electron microscopic (SEM) analysis were done with dehydrated, dried samples in high vacuum mode.

**RESULTS & DISCUSSION:** The overall structure of the cement revealed a droplet-like sub-compartmentation and partial positive staining for lipids with oil red. Histochemically, the most dominant staining of the cement was observed with BBS for basic proteins. Moderate PAS-positive regions indicated carbohydrates at the margins of the cement cones and Alcian blue staining was almost completely absent. Arnow staining was negative. TEM revealed a heterogeneous ultrastructure with locally elongated, electron dense material embedded in homogenous ground substance. In SEM, the surface of the cement droplets appeared rough. AFM revealed viscoelastic properties and pull-off tests the adhesiveness of the material.

**CONCLUSIONS:** The analysis reveal that tick cement consists of protein and lipid rich components and has viscoelastic properties.

**ACKNOWLEDGEMENTS:** Financial support was received from the Austrian Science Fund FWF (Project Number P 28962) and the COST Action CA15216 “European Network of BioAdhesives” ENBA
A culturing system for induction of autonomous pellet formation for chondrogenic differentiation

M. Fürsatz1,2, C. Gahleitner1, B. Schädl3, H. Redl2,4 S. Nürnberger1,2,4

INTRODUCTION: Scaffold free spheroid cultures are the current standard in vitro model for chondrocyte re-differentiation and chondrogenic stem cell differentiation. However currently used systems often have time and reagent intensive maintenance. Herein we present an efficient system for spheroid mass-production, by self-assembling of cell spheroids from monolayer, with promising application in cartilage regeneration.

METHODS: Standard cell culture dishes were compartmentalized using CO₂ laser engraving. Telomerase immortalized adipose derived stromal/stem cells (ASC/TERT1) and primary human articular chondrocytes (HAC) were seeded on these plates at a total amount of 1 x 10⁶ cells either alone or in co-culture (1:4,1:1,4:1 HAC:ASC/TERT1 ratios). Cells were further cultivated in chondrogenic media containing low doses of growth factors (1 ng/ml TGFβ-3 and BMP-6). Spheroid formation kinetics and controllability of size by variation of compartment size were investigated. Spheroids were analyzed using time-laps imaging, light-/electron-microscopy, (immuno-)histology (Alcian blue, collagen type 2 (Col2)). Additionally chondrogenic differentiation over the duration of 3 and 5 weeks was compared to standard pellet culture using (immuno-)histology and qRT-PCR (collagen type 1/2(Col1/2)).

RESULTS & DISCUSSION: Spheroid size was controllable by variation of grid size and yielded reproducible diameters (SD < 10%) with mean values of 340.9 µm and 134.4 µm for 3 mm and 1 mm grids respectively (p < 0.0001). Mature spheroids formed within 3 weeks for ASC/TERT1 monoculture and 1-2 weeks for HAC:ASC/TERT1 co-cultures, with significant difference in formation speed for 1:1 and 4:1 HAC:ASC/TERT1 ratio (p < 0.05 and p < 0.01 respectively). Histological analysis showed differences in matrix distribution between ASC/TERT1-only and co-cultures. When comparing grid plate and standard pellet culture derived cell spheroids histologically, similar or slightly improved matrix deposition in grid plate spheroids could be observed. First results showed that while ASC/TERT1-only spheroids had very low Col2 expression in PCR in both culture systems, co-cultures had similar Col2 expression in both systems, but showed increased Col2/Col1 ratio in grid plate culturing system.

CONCLUSIONS: The data herein presented show an efficient system for cell spheroid self-assembly from monolayer with highly reproducible spheroid size, and similar or improved differentiation capacity compared to standard pellet culture.

ACKNOWLEDGEMENTS: Financial support was received from the “Österreichische Forschungsförderungsgesellschaft” (FFG; Projectnr.: 867720). ASC/TERT1 were kindly provided by Evercyte GmbH.
In vitro Study of Ti-34Nb-6Sn alloy in mesenchymal stem cell culture for biomedical applications

INTRODUCTION: The increase in life expectancy of the population and the numerous traffic accidents have motivated the need for the development and improvement of orthopedic devices to replace the functionality of the bone tissue in the long term. Metallic devices are the most widely used, such as Ti-6Al-4V and Co-Cr alloys. However, they have cytotoxic nature over long periods, causing respiratory and neurological conditions. On the other hand, the Ti-Nb-Sn has no harmful elements, and its rigidity and mechanical strength are similar to the bone. In this work we performed a safety test, analyzing the biological effect of conditioned culture medium after the synthesis of the Ti-34Nb-6Sn alloy in stem cells derived from equine bone marrow (BM-MSCs).

METHODS: BM-MSCs were seeded at 1x10^5 cells/well for the cytotoxicity, osteogenic differentiation and wound healing assays. For these tests we conditioned the culture medium with the alloy and treated the cells at the respective times of each assay to evaluate this medium released particles that would be toxic in the main biological functions. After, we evaluate cell morphology and adhesion on the biomaterial by Scanning Electron Microscopy (SEM).

RESULTS & DISCUSSION: In 24h the conditioned medium did not promote harmful effects in the cells compared to the control (P> 0.05). We observed that the medium conditioned differentiation with the material did not influence the osteogenic differentiation since the lineage was confirmed with calcium marking by Alizarin red after 10 days. The treated group showed a significant migration in 24h. The cells seeded on the surface material presented fibroblastoid character in addition to being anchored and spreaded on its surface.

CONCLUSIONS: This material may be a good candidate for the development of orthopedic devices, because during the treatment the cells with material we did not found toxic effects.

ACKNOWLEDGEMENTS: Financial support was received from FAPESP (2017/13876-2), Institute of Technological Research State of São Paulo for materials development.
Mesenchymal stem cell-derived extracellular matrices assembled in the presence of high molecular weight hyaluronic acid exhibit anti-inflammatory properties

Cell-based therapies are facing many challenges as the hostile inflammatory and ischemic environment in the affected tissue impairs integration, survival and hence therapy efficacy upon direct implantation. Nevertheless, the cellular secretome was shown to augment tissue healing and even regeneration. So far, the major focus for the related mechanism of action lied on the soluble paracrine factors. We hypothesized that the insoluble fraction of the cellular secretome, namely the extracellular matrix (ECM), would also hold a pro-regenerative potential. Hence, we decided to engineer tailor-made ECM in vitro. Mesenchymal stem cells (MSCs) were allowed to assemble their ECM in the presence of exogenously added high molecular weight hyaluronic acid (HMWHA) to harness the anti-inflammatory and pro-regenerative potential of both components. Indeed, supplementation of HMWHA to human bone marrow MSC (bmMSC) cultures resulted in increased expression levels of anti-inflammatory cytokine interleukin 10. Addition of exogenous HMWHA over a time course of 2 to 6 days, enhanced the deposition of a bmMSC-derived ECM in a dose dependent manner. The ECM was enriched in provisional matrix components HA and fibrillar fibronectin (Fig. 1). Next, the engineered matrices were decellularized and investigated for their effect on macrophage polarization. THP-1 cells (human monocytic cell line) were differentiated into macrophages (MØ), seeded on decellularized ECMs and pulsed with pro-inflammatory factors to induce polarization into a pro-inflammatory phenotype (M1). As quantified by ELISA for TNFα, engineered matrices impaired macrophage polarization towards M1. The HMWHA-mediated enhanced deposition of an anti-inflammatory ECM enables us to construct a bio-instructive material to promote healing and regeneration in diseased tissues facing chronic inflammation.

Figure 1: HBMSCs cultures supplemented for 2 to 6 days with HMWHA (1 mg/ml) assemble fibronectin fibrils (green) depending on the HMWHA dose. Scale bar: 500 um.
In situ gellable hyaluronan based hydrogels with antimicrobial activity

\textbf{INTRODUCTION:} Hyaluronan derivative-based in situ gellable hydrogels were suggested as suitable materials for prevention of post-operative adhesions \cite{1}. The aim of this study was to develop an injectable hydrogel containing an antibacterial compound which would be easily delivered to the side of application, e.g. through minimally invasive procedures. The hydrogel should cover surrounding tissues in order to prevent organ adhesions. Moreover, the presence of antimicrobial agent should decrease the risk of post-operative infection.

\textbf{METHODS:} Hyaluronan polyaldehyde derivative (HA-CHO; degree of substitution 10 %; 30 mg/ml)-based matrix crosslinked by O,O′-1,3-propanediylbishydroxylamine (POA; 0,4 mg/ml) was designed to provide in situ gellable hydrogels with tunable time of gelation and viscoelastic properties. Triclosan/hydroxypropyl-β-cyclodextrin inclusion complex (TCS/CD) was used as antimicrobial component. Time of gelation and viscoelastic properties of hydrogel were evaluated. Moreover, cytotoxicity (ATP assay) and antimicrobial activity (diffusion plate method) of the developed material were evaluated.

\textbf{RESULTS & DISCUSSION:} TCS is a hydrophobic drug poorly soluble in water. It is well known in the field of coating implantable devices \cite{2}. The TCS/CD inclusion complex was prepared to solubilize the drug in water in order to produce a homogenous distribution of TCS in the hydrogel. Hydrogels containing TCS in concentration 0,1 and 1 mg/ml were prepared. Presence of the inclusion complex did not affect neither gelation time nor viscoelastic properties of hydrogels. Hydrogels containing 1 mg/ml TCS had a significant antimicrobial effect on all tested microbial strains. Viability assay proved that hydrogel extracts did not negatively affect viability of 3T3 mouse fibroblast cells.

\textbf{CONCLUSIONS:} New in situ gellable hyaluronan-based hydrogel with antimicrobial properties was designed. Further preclinical studies will be needed to evaluate its ability to prevent post-operative adhesions and infections.

Chitosan/hyaluronate blends and their modification as gradient materials for osteochondral tissue regeneration
M. Hunger, P. Domalik-Pyzik, J. Chłopek
Presenting Author: Martyna Hunger, hunger@agh.edu.pl
Department of Biomaterials and Composites, Faculty of Materials Science and Ceramics, AGH University of Science and Technology, Krakow, Poland

INTRODUCTION: Biomedical applications require specific properties of materials, such as biocompatibility, stability in physiological environment and appropriate mechanical strength. Polysaccharides, e.g. hyaluronates or chitosan are of particular importance here. However, relatively low mechanical properties of natural polymers make their application problematic. It may be overcome by forming blends or composites. Moreover, it is desirable to imitate biomimetic hierarchical structure [1-3].

METHODS: The aim of this research was to fabricate blends based on chitosan (CS, 2% w/v; 5% lactic acid) (Acros Organics, MW=100,000-300,000) and sodium hyaluronate (HA, 0-30% w/v; water) (Acros Organics), as well as to obtain composite systems with graphene oxide (GO, 0-3% w/w of CS) (ITME, Poland) and hydroxyapatite (HAp, 20% w/w of CS) (MKN-HXAP, 12 µm) as a basis for gradient materials development. Firstly, aqueous solutions of CS and HA were prepared and mixed at different ratios of CS:HA (10:90, 30:70, 50:50, 70:30, 90:10). To obtain composites, GO and HAp dispersions were separately prepared by sonication (30 min) and then added to the polymers mixture. Freeze-dried (72h, -80°C) scaffolds and films were fabricated and following properties were evaluated: microstructural (SEM), structural (FTIR-ATR), mechanical (static compression test) and surface (wettability).

RESULTS & DISCUSSION: Optimal proportion in blend was chosen – CS:HA 30:70. This material had the highest mechanical properties after compression test (Figure 1), as well as the best stability in water and PBS. The 30:70 blend was used to obtain composite systems, and then – hierarchical structures. The addition of GO to the blends improved the compression strength, and HAp made the blends more brittle – with their simultaneous additions it is possible to obtain gradient structure and control the properties. Preliminary in vitro cell culture studies showed promising results, detailed biological examination is planned.

CONCLUSIONS: The biomimetic hierarchical structures based on chitosan, sodium hyaluronate, graphene oxide and hydroxyapatite were fabricated. It seems that they possess promising properties as potential materials for osteochondral regeneration.

INTRODUCTION: Over the past years, the decellularization of peripheral nerves has been used to provide a natural substrate composed of nerve extracellular matrix without the resident cells to prevent the host immune response when transplanted in patients. Despite the existence of other protocols, as the Hudson and Sondell, they are either complex to prepare or the nerve extracellular matrix is slightly affected by the chemicals used, our aim is to find a new efficient decellularization protocol that is both easy to prepare and conserves well the nerve extracellular matrix.

METHODS: Rat Sciatic nerves were harvested and divided in 3 groups, each followed a different decellularization protocols, protocol 1 (already described in the literature for nerve decellularization), protocol 2 (described in the literature for tendon decellularization and here applied on nerves), protocol 3, a new protocol proposed by our group. Following decellularization, nerves were fixed and included in resin for light and electron microscopy analysis. Other parameters will be tested in the future such as mechanical testing and ex-vivo cytocompatibility.

RESULTS & DISCUSSION: Preliminary analysis in light and electron microscopy demonstrated that nerves decellularized using protocol 1 showed good tissue organization with intact collagen, but some axons with undamaged intracellular matrix integrates are still present. Nerves decellularized using protocol 2 showed rich matched connective matrix, no integral axons are present.

CONCLUSIONS: The combination of chemicals (several detergents at low concentration) with physical forces (agitation) can be a promising technique for nerve decellularization that is effective in removing cells and preserving ECM in short time nerve processing.

Engineering of in vitro vascular anastomosis under vascular endothelial growth factor (VEGF) gradients in a microfluidic device
M. Watanabe¹, R. Sudo¹,²
Presenting Author: Masafumi Watanabe, watanabe@sudo.sd.keio.ac.jp
¹School of Integrated Design Engineering, Keio University, Yokohama, Japan, ²Department of System Design Engineering, Keio University, Yokohama, Japan

INTRODUCTION: In vitro engineering of vascular anastomoses is critical for the development of transplantable tissue-engineered grafts, because rapid blood perfusion is required for the maintenance of implanted tissue grafts. However, the process of vascular anastomosis between host and engineered vessels remains unclear due to difficulties in observing vascular anastomosis after transplantation. Therefore, we aimed to establish an in vitro vascular anastomosis model in a microfluidic device using human umbilical vein endothelial cells (HUVECs) mesenchymal stem cells (MSCs).

METHODS: Microfluidic devices were designed and fabricated with polydimethylsiloxane, which comprised two side microchannels sandwiching a gel microchannel. The central gel channel was filled with fibrin/collagen gel. A side channel was filled with HUVECs through an outlet of the channel, while the other channel was filled with HUVECs and MSCs at ratios of 2:8, 5:5, and 8:2 (Figure 1). Constructed vascular anastomoses were observed by confocal microscopy. Chemical gradients of vascular endothelial growth factor (VEGF) in the gel were calculated by Fick’s second law using COMSOL Multiphysics. VEGF distributions in the gel at 24 h were calculated.

RESULTS & DISCUSSION: Firstly, HUVECs were cultured in both side channels to confirm the ability of vascular anastomosis formation. Contrary to expectations, vascular sprouts were not formed at least by day 10. In addition, the simulation results indicated that VEGF gradient was not maintained at 24 h when HUVECs were seeded in both microchannels. Next, we added MSCs to the HUVEC monoculture condition to induce angiogenesis. Confocal images showed that vascular geometry was dependent on HUVEC:MSC ratios. At a HUVEC:MSC ratio of 2:8, vascular networks extended from both microchannels formed vascular anastomoses by day 10. Quantitative analysis showed that the number of vascular anastomoses was significantly increased at the HUVEC:MSC ratio of 2:8, which was >3-times greater than the other ratios (5:5 and 8:2). Moreover, the simulation results showed that the steepest VEGF gradient was maintained at the HUVEC:MSC ratio of 2:8. Furthermore, live-cell imaging revealed the process of vascular anastomosis. Vascular anastomoses in our model were formed through a multistep process such as EC migration and vascular contact. Moreover, the detailed structure of vascular anastomosis indicated that vascular anastomosis was constructed with continuous lumens during days 8–10.

CONCLUSIONS: In summary, we successfully established an in vitro vascular anastomosis model in a microfluidic device. Furthermore, our data showed that VEGF gradients played important roles in vascular anastomosis formation. This model will provide insights for both the development of tissue-engineered grafts and for the construction of large tissues by assembling multiple tissue-engineered constructs.
3D extracellular matrix derived model of alveolar Rhabdomyosarcoma
M. Saggioro¹,², M.G. Muraro³, S. D’Agostino¹,², G. Germano ², E. Poli¹,², L. Tombolan¹, P. Bonvini², G. Bisogno¹, P. Gamba¹, I. Martin³, M. Pozzobon¹,²

INTRODUCTION: Alveolar Rhabdomyosarcoma (ARMS) is one of the most aggressive pediatric soft tissue sarcoma with a high tendency to metastasize [1]. The need of new models to study cell-extracellular matrix (ECM) interactions are needed. Integrins are a class of transmembrane adhesion molecules that mediate cell survival, differentiation, migration and differentiation [2]. The aim of this study is to create an engineered 3D ARMS model using a U-Cup bioreactor. We will investigate the protein expression with specific attention on the role of integrins in ARMS metastatic migration.

METHODS: ARMS xenografts were obtained from subcutaneous injection of RH30 (ARMS cell line) cells in immunodeficient mice. ECM composition was determined by proteomic analysis. ARMS cells were seeded in a 3D collagen scaffold cultured in a perfusion bioreactor (U-Cup). Cells before and after 3D culture were analyzed by qPCR, flow cytometry for the expression of a panel of integrins and CXCR4. MMPs expression was evaluated by zymography.

RESULTS & DISCUSSION: After ARMS xenografts characterization, proteomic analysis was performed: the main components of the ECM will be used to enrich the collagen scaffold. Preliminary data culturing RH30 cells in U-Cup bioreactor with collagen scaffold showed upregulation of ITG ⁵ and CXCR4 receptor compared to 2D condition. Expression of MMP-9 and MMP-2 was assessed by zymography comparing the expression of these MMPs in ARMS cells cultured in 2D versus 3D dynamic culture and isolated from the xenograft samples.

CONCLUSIONS: We demonstrated that our 3D ARMS model better recapitulates the complex in vivo environment than 2D, enhancing the expression of MMPs, ITG ⁵ and CXCR4. The important interaction between ITG ⁵ and MMP-2 [3] will be deeper studied in a more representative engineered 3D scaffold to shed light on the complex cross talk between cell-ECM interaction and metastatic progression.

INTRODUCTION: Osteoarthritis (OA) is a degenerative joint disease. The pathogenesis is not fully understood but studies show that inflammation following joint injury plays a key role in its onset. Microspheres (µSp) releasing anti-inflammatory agents could potentially attenuate the inflammatory response and the inflammatory milieu in the degenerating joint and prevent OA. Herein, negatively charged microspheres (µSP) ionically complexed with positively charged anti-inflammatory cytokines IL-4, or IL-10 or IL-13 were developed and tested in inflammatory in vitro chondrocyte mouse models.

METHODS: Gelatin µSP using non-ionic surfactants 0.1% vol L101 vs. Tween 20 were produced and then cross-linked with genipin. Cytotoxicity of the surfactants was measured using proliferation and metabolic assays, µSP were characterized for average size (ImageJ), zeta potential (Zetasizer), and collagenase-mediated degradation. 200ng of IL-4, IL-10 or IL-13/mg µSp were loaded and release was measured (ELISA). µSp were then tested in murine chondrocyte ATDC-5 inflammatory in vitro models simulated with IL-1β (2 ng/ml) or LPS (200 ng/ml). Loaded, unloaded µSp vs. bolus treatment (10 ng/ml) were added. Nitrite (NO) was measured (Griess assay).

RESULTS & DISCUSSION: Surfactant treatment had no effect on metabolic activity but Tween resulted in a higher cell viability at day 7 (p<0.001). Therefore µSp (avg. diameter 15+/±4.2 μm; were produced using Tween. Increasing the density of genipin crosslinking decreased the zeta potential facilitating loading with cytokines. µSp loaded with IL-4, IL-10 or IL-13 resulted in a loading efficiency > 80%. Upon collagenase degradation the cytokines were incrementally released for up to 7 days. To mimic OA, mouse chondrocytes were activated with and without IL-1β or LPS. At day 3, NO chondrocyte production showed that the IL-4 and IL-13 released from the µSp significantly reduced NO production vs. control (unloaded µSp), while IL-10 only showed marginal effects.

CONCLUSIONS: These results demonstrate that cross-linked gelatin µSp can be used to deliver anti-inflammatory cytokines. Moreover, the inflammation-dependent degradation and release of IL-4 or IL-13 by the stimulated cells can be harnessed to minimize unnecessary drug release during periods of low disease activity thus enhancing their therapeutic effect. Hence, µSP could minimize inflammation and immuno-mediated injury of chondrocytes and alleviate post-traumatic inflammation in OA.
Dental pulp stem cells and leukocyte- and platelet-rich fibrin for articular cartilage repair

\textsuperscript{3}Department of Musculoskeletal Biology, Institute of Ageing and Chronic Disease, University of Liverpool, Liverpool, United Kingdom

\textbf{INTRODUCTION:} Osteoarthritis (OA) is a degenerative and inflammatory condition of synovial joints with irreversible loss of supportive cartilage matrix. Dental pulp stem cells (DPSCs) can be differentiated into cartilage-producing cells and secrete numerous growth factors associated with tissue repair and immunomodulation. Moreover, leukocyte- and platelet-rich fibrin (L-PRF), a blood-derived and clinically applied biomaterial, has recently emerged as a promising treatment in regenerative medicine due to its growth factor content and supportive fibrin matrix. The main goal of this study is to evaluate whether DPSCs and L-PRF are promising treatment strategies in OA via immunomodulation and stimulation of cartilage regeneration.

\textbf{METHODS:} First, DPSCs were subjected to a chondrogenic differentiation system, with or without L-PRF conditioned medium (CM) (5\% and 25\%) and exudate (3\%), and compared to bone marrow-mesenchymal stem cells (BM-MSCs) via (immuno)histochemistry. Secondly, immature murine articular chondrocytes (iMACs) were isolated and cultured with either DPSC CM, L-PRF CM (5\%, 25\% and 50\%) or exudate (1\%, 3\% and 5\%). Healthy iMAC survival, proliferation and cartilage-specific extracellular matrix production were assessed. Finally, IL-1β- and TNFα-stimulated iMAC viability, cartilage matrix production and inflammatory cytokine secretion were analyzed.

\textbf{RESULTS & DISCUSSION:} Preliminary data suggest that L-PRF does not increase the expression of chondrogenic markers after differentiation. DPSC and L-PRF CM have a significant pro-survival and proliferative effect on iMACs. IL-1β- and TNFα-stimulated iMAC viability follows an increasing trend after exposure to L-PRF and DPSC CM. iMACs cultured in DPSC and L-PRF CM show a more cartilage-like matrix production. DPSC CM appears to prevent and decrease nitrite secretion in IL-1β- and TNFα-stimulated iMACs.

\textbf{CONCLUSIONS:} Our in vitro data show that DPSCs and L-PRF are a promising treatment option for OA via secretome-mediated effects. Our final goal is to test in vivo if DPSCs and L-PRF improve cartilage repair and have immunomodulatory effects in an ovine model of OA.

INTRODUCTION: Recapitulating tissue elasticities can direct mesenchymal stem cell (MSC) differentiation through mechano-transduction [1]. However, it is unknown how elasticity affects MSC metabolism which could be an important feature to enhance differentiation and mineralisation. To delineate this, our study investigates real-time MSC metabolism and differentiation on substrates of varying stiffnesses using a miniaturized optically accessible flow bioreactor (MOAB) with Fluorescence Lifetime Imaging Microscopy (FLIM).

METHODS: Polyacrylamide gels of varying stiffnesses were fabricated via UV-crosslinking, seeded with MSCs and placed within MOABs with or without continuous flow of 5 µL/min. Real-time FLIM was performed to quantify free and protein bound nicotinamide adenine dinucleotide (NADH). Computational Fluid Dynamic (CFD) analysis was used to predict the velocity field and shear stress profile within the MOAB. The effect of substrate stiffness and flow, in combination or independently; on MSC metabolism was investigated.

RESULTS & DISCUSSION: MSCs cultured on substrates exhibited distinct metabolic patterns over 14-days, observed as early as day 3. Overall, by day 10, soft substrates induced a more glycolytic response while cells grown on stiffer substrates displayed a transition to oxidative phosphorylation, measured by protein-bound NADH fraction of the fluorescence lifetime decay). CFD results showed uniform shear stress profile within the chamber in the presence of non-porous polyacrylamide scaffolds with values lower than 3 mPa at a flow rate of 5 µL/min.

CONCLUSIONS: Monitoring the effect of stiffness and flow in real-time with FLIM was achieved via the optically transparent miniaturized system. Matrix stiffness induced metabolic perturbations in MSCs up to 14 days.

ACKNOWLEDGEMENTS: This project received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No. 825159-MOAB).

INTRODUCTION: Science mapping analysis (SMA) has been described as “a spatial representation of how disciplines, fields, specialties, and individual papers or authors are related to one another” [1]. This methodology enables the user to explore the underlying relationships between apparently different literature [2].

METHODS: The search strategy (“TISSUE ENGINEER*” or “TISSUE-ENGINEER*”) was entered as the topic in the SCI-Expanded collection of Web of Science (WoS) for the period between 1991 and 2016. Reviews, book chapters, proceedings papers and meeting abstracts were excluded. Author’s Keywords and Keywords Plus were retrieved to perform a longitudinal SMA with SciMAT software to elucidate the main concepts arising from TE [3]. Clustering of different keywords into themes was performed and a network of different themes was obtained. Callon’s centrality and density was measured to setup a 2d layout that could divide each theme in 4 categories: “motor themes”, “basic and transversal themes”, “highly developed or isolated themes” and “emerging or declining themes”.

RESULTS & DISCUSSION: The present cognitive analysis allowed us to identify three main vectors: cells, material biodegradation and growth factors. TE has evolved from a focus on differentiated cells such as chondrocytes, toward a specific type of stem cell (MSC) with a high capacity for differentiation. Since the emergence of biomaterials in the first subperiod, “biodegradation” appeared as a motor theme not only in the first but also in the second subperiod. However, the development of new biomaterials with biodegradable properties, such as hydrogels, has displaced biodegradation as a motor theme. The selection of appropriate growth factors to influence new tissue activity was the third vector present in all three subperiods.

CONCLUSIONS: A better understanding of the cognitive structure behavior of tissue engineering can contribute not only to our knowledge of the conceptual evolution, its main historic vectors, and other research foci, but can also help administrative authorities to better plan funding allocations.

INTRODUCTION: Mesenchymal stem cells (MSC) previously demonstrated to have epithelial differentiation capability [1]. Therefore, complex artificial tissue models containing epithelial layers could be generated using MSC as alternative cell sources, since human keratinocytes are difficult to isolate and expand under culture conditions. In fact, several previous reports demonstrated that human artificial tissues can be generated without the need of obtaining epithelial cells [2]. Here, we investigated the capability of 4 different MSC sources to generate a functional skin epidermis.

METHODS: Human skin substitutes (HSS) were developed by tissue engineering protocols using alternative epithelial cell sources. Briefly, a stromal substitute was generated using a mixture of human fibrin and 0.1% type VII agarose. These hydrogels contained 500,000 skin fibroblasts. For the generation of a epithelial layer, 250,000 MSC obtained from adipose tissue (ADSC), dental pulp (DPSC), Wharton’s jelly (WJSC) or bone marrow (BMSC) were seeded on top of the artificial stroma. After 28 days in culture, HSS were grafted on the back of nude mice for in vivo evaluation during 15 and 30 days. Surface and morphology of MSC differentiated to skin epithelium were assessed using SEM and histological methods.

RESULTS & DISCUSSION: The analysis of the epithelial surface of the 4 different HSS demonstrated that all MSC types used as epithelial-like substitutes were able to develop a well-structured epithelium. At the beginning, all cells had the typical spindle-like shape, elongated morphology of native MSC. However, cells tended to partially change their morphology and acquire a more polygonal shape with time in culture, especially in the case of WJSC and BMSC at day 28. Once grafted in vivo, the 4 MSC types showed a clear morphological change, and cells became very flat and polygonal, showing keratinization and desquamation signs, especially after 30 days of in vivo development.

CONCLUSIONS: our results demonstrate the partial epithelial differentiation capability of ADSC, DPSC, WJSC and BMSC, which could be used for the generation of bioengineered human skin substitutes without the need of obtaining keratinocyte cell cultures.

INTRODUCTION: Heart failure is a global health epidemic, with myocardial infarction being the most common cause of heart failure. Human induced pluripotent stem cell-derived cardiomyocytes (iPSC-CMs) have shown great promise for myocardium repair, however their immaturity and poor engraftment are still challenges. Recently, we showed that well-ordered hexagonal fiber scaffolds obtained by melt electrowriting (MEW) can support contracting human iPSC-CMs and drive their maturation. Here we hypothesized that miniaturisation of the hexagonal microstructures will improve cellular adhesion, and co-culturing of iPSC-CMs with other native cell types, such as cardiac fibroblasts (FBs) and endothelial cells (ECs), will further enhance iPSC-CM maturity and functionality.

METHODS: Hexagonal microarchitectures were fabricated with a custom-built instrument [2]. Miniaturisation was systematically investigated according to key MEW parameters. After fabrication, hexagons were structurally and mechanically characterized. MEW meshes then were combined with a collagen-based hydrogel containing iPSC-CMs (CMs), human foetal cardiac fibroblasts (FBs) and human umbilical vein endothelial cells (ECs) using three combinations (100% iPSC-CMs, 90% iPSC-CMs + 10% FBs or 90% iPSC-CMs + 5% FBs + 5% ECs). Functionality, morphology and maturation were evaluated within a one-week culture period using analysis of beating rate, immunofluorescent staining, anisotropy and gene expression.

RESULTS & DISCUSSION: Hexagonal pores with 200 µm side lengths were successfully manufactured. In vitro culture shows that beating rate is enhanced in the CM + FB coculture, whereas CM + FB + EC coculture causes a decrease in contraction rate over a 7-day culture period. Immunofluorescent staining showed that CM alignment was enhanced in the CM + FB coculture after 4 days, compared with both the CM only and CM + FB + EC groups. Increased cell coupling was observed, resulted in larger tissue-like structures in both the CM + FB and CM + FB + EC groups in comparison to the CM only group. Furthermore, diffusion tensor imaging revealed that the addition of FBs to the patches increased anisotropy and reduced mean diffusivity, closer mimicking values of the native myocardium.

CONCLUSIONS: The present study demonstrated that MEW technology can print unique fibre designs at micrometre resolution. Co-culturing iPSC-CMs with other cardiac nonmyocytes can further enhance maturation and efficacy of myocardial patches, in comparison to CMs alone. In the current research, we are further optimizing our concept through local and controlled deposition of different cell types to drive this technology towards preclinical studies.
Multi-scale fabrication of an osteochondral implant with hierarchy in fiber orientation and cell distribution

INTRODUCTION: Osteochondral defects are hard to heal due to limited regenerative capacity of cartilage tissue. Recently, we showed to successfully include melt electrowriting (MEW) in the bioprinting process with a single-step approach, which allowed for control over cell deposition and MEW-fiber deposition. However, convergence of biofabrication technologies is still in its infancy. In this study, we increased complexity, and fabricated a zonal osteochondral plug with a bi-layered cartilage layer, which was compared to an osteochondral plug with a uni-layered cartilage layer. The performance of the zonal plug was evaluated in vivo.

METHODS: To recreate the zonal cartilage architecture in both cells and fibers, the zonal osteochondral plug (diameter = 6 mm, h = 7.5 mm) consists of printable calcium-phosphate (pCaP), two architectures of MEW-fibers, (polycaprolactone), and different densities of articular chondroprogenitor cells (ACPCs), embedded in 10% gelatin-methacryloyl (gelMA). The non-zonal osteochondral plug consists of pCaP, one architecture of MEW-fibers, and one ACPC density. After fabrication, osteochondral plugs were cultured for 4 weeks, the compressive Young’s modulus and complex shear modulus were measured, and cartilage like tissue formation was quantified (GAG/DNA, Dimethylmethylene blue (DMMB)/Picogreen) and confirmed with histology. Zonal plugs were implanted in Shetland ponies (n = 8), gait analysis (over time) and X-rays (after 3 months) were performed, and tissue formation was evaluated after 6 months of implantation.

RESULTS & DISCUSSION: Fabrication of a multi-phasic osteochondral plug in a single step approach was successful. An increase in GAG/DNA was found after 4 weeks of culture, and newly formed cartilage-like tissue was evenly dispersed throughout the sample. The cartilage layer of the fabricated zonal plugs showed an increase in compressive Young’s modulus from 300 to 700 kPa and an increase in complex shear modulus from 40 to 80 kPa compared to the non-zonal cartilage layer. Implantation of the osteochondral plugs was successful, no discomfort in gait analysis was shown, and bone tissue infiltration was found 3 months after implantation.

CONCLUSIONS: Incorporation of MEW in the extrusion based bioprinting process allows for control over fiber architecture and cell distribution. Fabrication of a cartilage layer with hierarchy in cell density and fiber orientation increases the mechanical properties of the cartilage layer, while not limiting cartilage-like tissue formation. Although bone infiltration in the plugs is found after 3 months and the ponies do not show discomfort, end stage in vivo evaluation (March 2019) will reveal if the zonal implants are successful for osteochondral repair.

INTRODUCTION: Poly(ester urea)s (PEUs) are a new class of biodegradable and bioabsorbable α-amino acid-based polymers for tissue engineering [1,2]. This work evaluates the chondrogenic potential of 3D printed PEU scaffolds for the first time and compares it to poly(caprolactone) (PCL).

METHODS: PEU and PCL scaffolds were fabricated using a 3D bioprinter (3D Discovery, regenHU) equipped with a screw-assisted extrusion head and a 330 µm diameter nozzle, with a lay-down pattern of 0/90°. Scaffolds were characterized by scanning electron microscopy (SEM), microcomputed tomography (micro-CT), nanoindentation, compression tests, and water contact angle (WCA). The response of seeded cells of the TC28a2 human chondrocyte line was evaluated in terms of cell morphology, metabolic activity and gene expression for 7, 14 and 21 days using the resazurin reduction assay and qPCR.

RESULTS & DISCUSSION: SEM and micro-CT revealed PEU and PCL scaffolds with filament diameter of approximately 320 µm, interconnected pores of quadrangular shape, homogeneous pore distribution and similar porosity (63.1% and 62.4% respectively). PEU scaffolds were more hydrophilic (WCA: 52.7°) and had lower nanoindentation hardness (0.20-0.33 GPa) and compressive modulus (60.2 MPa) than PCL (86.9°, 0.27-0.47 GPa, 79.8 MPa). Both materials supported human chondrocyte adhesion. Cells on PEU had higher metabolic activity, expression of chondrogenic genes ACAN and COL2A1 and lower expression of COL1A1, suggesting a more chondrogenic phenotype.

CONCLUSIONS: Taken together, these data suggest that PEU is a promising material for cartilage tissue engineering probably due to its lower hardness and compressive modulus, and higher hydrophilicity compared to PCL.

INTRODUCTION: Sucrose acetate isobutyrate (SAIB), a synthetic disaccharide with extraordinary rheological characteristics. Herein, it is proposed to explore the potential of SAIB in tissue engineering scaffolding applications, by green processing SAIB with chitin using ionic liquids (ILs).

METHODS: SAIB and chitin were dissolved individually in IL, and then mixed by adding the SAIB/IL solution to the chitin/IL solution. Then the solution was transferred to silicone molds (d=8 mm, h=2 mm), followed by gelation, while immersing in solvents - water (A) or water:isopropanol (1:1, B), to obtain the chitin/SAIB gels (SC-A and SC-B, respectively). Chitin/IL scaffolds (C-A and C-B) were used as controls. These were placed in caped flasks at 150 rpm with daily solvent change, and aliquots were collected to measure the conductivity and follow the removal of the ILs. SAIB/Chitin gels were freeze-dried. The physicochemical characterization performed comprised rheology, FTIR, XRD, SEM, microCT and swelling. The in vitro studies performed covered cytotoxicity, cell damage (ISO10993) and cell morphology.

RESULTS & DISCUSSION: The presence of the molecules and the absence of ILs, was confirmed by FTIR and XRD techniques. By SEM and microCT was possible to observe the morphological features of the produced scaffolds, that resembles the typical morphology of aerogels (SC-B, C-A, C-B) but also compact structures (SC-A). The presence of SAIB increased about 4 times the adhesivity (N.s) of the scaffolds and, at the same time, has halved the strength of the structure (G'/Pa).

CONCLUSIONS: It is shown the potential of the used approach, to apply these scaffolds in tissue engineering.

INTRODUCTION: Hydrogels hold a great potential on the scope of cell-based therapies and can be used to unravel several bottlenecks of these approaches \cite{1}. Herein, we intend to develop injectable manganese-based methacrylated gellan gum hydrogels that can be monitored via MRI imaging.

METHODS: 0.75\% (w/v) methacrylated gellan gum (GG-MA) solutions were supplemented with 0.1 and 1 mM of MnCl\textsubscript{2} (Sigma-Aldrich) and further crosslinked with artificial cerebrospinal fluid (aCSF). The resulting hydrogels were characterized regarding their injectability, stability and MRI signal. As proof-of-concept, human-derived adipose stem cells (hASC) were encapsulated in 0.1 mM MnCl\textsubscript{2} GG-MA hydrogels and cultured for 7 days. During the culture period, cell viability was assessed using Live/Dead staining kit (Thermo Fisher).

RESULTS & DISCUSSION: All the prepared formulations are injectable, with the force needed to inject gel solution being lower or similar to the force needed to inject water. After the 7 days of incubation in aCSF, hydrogel degradation was approximately 20\% for all the formulations tested. T1-weighted MRI scans showed that formulation with 0.1mM MnCl\textsubscript{2} exhibits a higher MRI signal. Therefore, in vitro studies were performed using this condition. hASCs encapsulated into hydrogel fibers remained alive up to 7 days of culture.

CONCLUSIONS: Manganese-based GG-MA hydrogels were successfully prepared. These hydrogels hold great potential for image-guided cell delivery approaches, when minimally invasive procedures are envisaged.

Mechanical suitability of a decellularized extracellular matrix (dECM) hydrogel for vocal fold tissue engineering

M. Brown¹, N.Y.K. Li-Jessen.¹,²,³
Presenting Author: Mika Brown, mika.brown@mail.mcgill.ca
¹Biological and Biomedical Engineering, McGill University, Montréal, Canada ²School of Communication Sciences and Disorders, McGill University, Montréal, Canada ³Otolaryngology – Head and Neck Surgery, McGill University, Montréal, Canada

INTRODUCTION: Existing biomaterials aimed toward vocal fold (VF) regeneration have failed to augment VF function long-term. These materials degraded rapidly and did not provide sufficient mechanical strength for regeneration of functional VF [1]. In this work, the mechanical properties of a decellularized extracellular matrix (dECM) hydrogel were compared to a collagen and hyaluronic acid (CHA) hydrogel.

METHODS: Porcine VF were dissected, decellularized, homogenized, solubilized with pepsin, and incubated to fabricate 1.5% dECM hydrogels [2]. Collagen and HA solutions were mixed 1:1 and gelled at 37 °C to prepare control CHA hydrogels. To analyze gelation kinetics, frequency dependence, and the deformation limit, each hydrogel underwent 2 h time sweeps, frequency sweeps from 1-10 Hz, and amplitude sweeps from 1-100% strain using a rheometer. Swelling tests were performed over a 21-day period by incubation in PBS. Enzymatic degradation kinetics were determined from residual mass by incubation in 0.05% collagenase.

RESULTS & DISCUSSION: The 1.5% dECM hydrogel gelled in 1 h, and the CHA hydrogel in 20 min. Both gels demonstrated storage moduli (G') greater than loss moduli (G'') and their G' were above 100 Pa, within the lower limit of human VF G' [3]. Linear frequency dependence was found for both gels, similar to human VF. The deformation limit of the dECM hydrogel was 44.97 ± 7.29%, above the 30% limit of human VF and significantly greater than that of CHA, 20.31 ± 4.65% (p < 0.05). Both dECM and CHA gels reached their maximum swelling ratios after 1 day, 4.37 ± 0.14 and 2.81 ± 0.33 times their dry mass, respectively (p < 0.005). On day 21, the 1.5% dECM gel retracted by 78% (p < .001) and the CHA gel by 68% (p < .05) from day 1. When incubated with 0.05% collagenase, both hydrogels degraded in 3.5 days.

CONCLUSIONS: The 1.5% dECM hydrogel had mechanical properties comparable to native VF tissue. However, their rapid gel retraction and degradation might not be favorable for long-term VF tissue reconstruction.

The effect of Wharton jelly-derived mesenchymal stem cells and their conditioned media in the treatment of rat spinal cord injury
M. Chudickova, I. Vackova, L. Urdzikova-Machova, S. Kubinova
Presenting Author: Milada Chudickova, milada.chudickova@iem.cas.cz
Institute of Experimental Medicine, Czech Academy of Sciences, Prague, Czech Republic

INTRODUCTION: Spinal cord injury (SCI) repair is a great challenge in tissue engineering and regenerative medicine. One of the treatment approaches represents transplantation of mesenchymal stem cells (MSCs), which possess anti-inflammatory, anti-apoptotic and generally supportive impact in wounded tissues by the paracrine effect. However, survival rate of transplanted MSCs is limited. Application of conditioned media (CM) derived of MSCs is an admitted approach how to bypass these limitations. Here we compared the effect of application of MSCs and their CM in the treatment of SCI in rats.

METHODS: We used MSCs derived from Wharton’s jelly of umbilical cord (WJ-MSCs), which display high proliferative potential and produce large amounts of neurotrophic and growth factors. 1.5 million of WJ-MSCs and their CM, pooled from three different donors, were intrathecally transplanted in three doses 1st, 2nd and 3rd week after the induction of balloon compression lesion.

RESULTS & DISCUSSION: The behavioural tests (Beam walk, BBB-test, plantar test) showed significant improvement after all three treatments (CM, WJ-MSCs and non-conditioned medium with ITS), in comparison with non-treated controls. Significant improvement in all behavioural tests was found after the treatment with WJ-MSCs, CM as well as control non-conditioned medium in comparison with the saline controls. CM application resulted in significant improvement in Beam walk time and score and plantar test in comparison with WJ-MSCs and control medium. Immunohistochemical stainings (GAP43, GFAP) and Luxol-fast blue are evaluated in order to determine tissue sparing, axonal growth and glial scarring. qPCR analysis will determine changes in expression of genes related to inflammatory reaction, apoptosis, axonal growth, growth factors and astrogliosis.

CONCLUSIONS: We propose that both, hWJ-MSCs and their CM have considerable effect in the functional improvement of motor and sensory functions after SCI and that the paracrine effect of direct cell transplantation can be replaced by the CM derived from these cells.

INTRODUCTION: Many studies have successfully replicated vascular pattern by 3D fiber printing, microscale continuous optical bioprinting (µCOB), and the use of PDMS molds etc.[1-2]. Even though these approaches had generated well-organized capillary-like structure in vitro, it took 4 to 7 days of implantation and demonstrated poor functional anastomoses between branches and host to form vascular network in vivo. In our study, we can create thick viscous finger pattern similar to native vascular network by Hele-Shaw cell within 5-10 seconds with the capability of controllable resolution in width of branches and size of capillary network. Also, this technique is easy to apply to create functional lumens with core-shell structure [3]. Thus, we adopt this technique into vascular tissue engineering to create the three-dimensional (3D) large and thick vascularized tissue construct by precisely controlling the cell spreading, growth direction, and further to engineer adequate vascular network in vitro rapidly.

METHODS: We successfully created vascular-like structures that obey Murray’s law by viscous fingers using the Hele-Shaw cell. It refers to a high-viscosity fluid driven by a low-viscosity fluid between parallel plates, and a finger-like type is formed between the fluid interfaces within 10 seconds.

RESULTS & DISCUSSION: By controlling properties of viscous solutions, pressure gradient (\(\nabla p\)) and surface tension coefficient (\(\sigma\)) in Hele-Shaw cell, various size of network structures (5-20 cm²), with controllable length (0.6-1 cm) and the width (100-400 µm) of fingers in a short time (5-10 s) were demonstrated. Mesenchymal stem cells (MSCs) were successfully encapsulated and patterned into vascular-like gelatin methacrylate hydrogel (GelMA) fingers for 3D cell patterning within 5-10 seconds. Further, we generate lumens surrounded by multiple hydrogel layers for dynamic microfluidics culturing, which extends the potential for modeling functionality of blood vessel in vivo.

CONCLUSIONS: Vascular-like fingers with controllable size, thickness and width of branches created by Hele-Shaw cell can be generated within 10 seconds. Additionally, this new developed technique can create core-shell structure by two different liquids in couple minutes. Our 3D cell patterning technique opens new avenues for the fabricating and investigating thick vascularized tissues for both ex vivo and in vivo applications.

INTRODUCTION: Although regenerative medicine and tissue engineering technologies have been developed dramatically, there are still many difficulties for the organ regeneration, especially, in the field of regenerative kidneys. Large numbers of chronic kidney disease (CKD) patients are still waiting for the organ transplantation using brain dead and living donor kidneys. To solve this problem, the whole organ decellularization and recellularization techniques have been actively investigated using various kinds of animals due to the existence of perfect vascular net-work systems. In this case, for the realization of renal function, endothelialization on the wall of renal ECM vessels is one of key factors and also it should be considered forming blood vessels of organ tissue for delivery nutrients and oxygen to the other type of cell. In this study, we used endothelial cell for regenerate blood vessel in the recellularized kidneys and investigated the stability of renal vessels by in-vitro approaches.

METHODS: Rat kidneys were extracted from over 8 weeks old rats and cannulated for the decellularization. For the decellularization, we used 1% Sodium dodecyl sulfate (SDS) and 1% Triton X-100 agents. Decellularized kidneys were pre-incubated in culture medium for 1 hour. Endothelial cells were detached by trypsin treatment and seeded on vascular ECM in acellular scaffold through renal artery. Culture medium was perfused with 1.5ml/min flow rate for 3 days, 1 week and 2 weeks. To confirm the attachment of endothelial cells on the vessel walls in ECM kidney scaffolds and cultured for 3 days, 1 week and 2 weeks. Distribution of endothelial cells and lining view in recellularized kidney were observed by H&E staining. Endothelial cells and angiogenesis markers like Tie-2, Tie-1, PECAM-1 were analyzed by FACS after detach endothelial cells by recellularized ECM kidneys.

RESULTS & DISCUSSION: Rat kidneys were decellularized successfully with 1% SDS and 1% triton X-100. Endothelial cells were attached well on the vessel walls in ECM kidney scaffolds and cultured for 3 days, 1 week and 2 weeks. Distribution of endothelial cells and lining view in recellularized kidney were observed by H&E staining. Endothelial cells and angiogenesis markers like Tie-2, Tie-1, PECAM-1 were analyzed by FACS after detach endothelial cells by recellularized ECM kidneys.

CONCLUSIONS: The study of recellularized ECM kidney scaffold with endothelial cell is preliminary study for protecting immune rejection response or blood clot by the thrombosis. Researches about endothelium regeneration and vessel formation mechanism of recellularized kidney in in-vivo need to be performed.

INTRODUCTION: Exosomes are small extracellular vesicles released by different kinds of cells. These vesicles involve in intercellular communication by transferring bioactive molecules which are supposed to be useful in cardiovascular diseases (CVDs). We investigated the role of exosomes in different types of CVDs. In addition to pathogenesis, therapeutic, diagnostic, and prognostic roles of exosomes, we discussed a variety of progenitor stem cells and their exosomes. Routes of exosome delivery to target tissue was also mentioned.

METHOD: The search keywords were "exosome, myocardial infarction, pulmonary hypertension, cardiomyopathy, valvular heart disease, and arrhythmia" in Google scholar and PubMed databases. Most articles are dated after 2012.

RESULTS & DISCUSSION: Exosomes are protective particles in atherosclerosis and therapeutic agents in 1950Wharton’s jelly mesenchymal stem cells, and induced pluripotent cells, have shown to be potential bio-factory for therapeutic exosomes which can be delivered by different routes including intramyocardial, intraperitoneal, and intravenous. It seems exosome quantity or content are valuable criteria for adding to traditional risk assessment table of cardiovascular events which makes it more precise for predicting MI prognosis. Some of exosome benefits compared to cell or liposome therapy are less immune provocative, longer lasting, and able to be stored at −70°C for several months. Ischemic heart disease [1]. In pathological states, they induce disease in healthy models [2] and provoke cardiomyopathy in diabetic patients. Exosomes may act as microRNA carriers which gives them the ability to work as biomarkers or targeted therapy [3]. Human cardiac progenitor cells, bone marrow and

CONCLUSIONS: Exosomes are new potential diagnostic and therapeutic agents in CVDs. They have the capability to be a new candidate as prognostic markers. It seems that exosome therapy may have a very important position in cardiovascular disease in the future.

INTRODUCTION: This research focused on therapeutic effects of placenta-derived mesenchymal stem cells (MSCs), their conditioned media and their exosomes on tumors, to understand whether these features of MSCs in cancer therapy are capable of being combined in order to achieve an efficient anti-tumor strategy.

METHODS: The relevant articles published from 2007 until 2019 were selected by using “exosome”, “mesenchymal stem cell”, “cancer” and their MESH terms as keywords for searching in PubMed, Scopus and Google scholar databases.

RESULTS & DISCUSSION: Using MSCs in treatment of cancer has benefits including tumor tropism, and delivery of antitumor biomolecules. Multidrug efflux pumps, which are highly expressed in MSCs seem to be useful in modulating adverse effects of drugs [1]. These cells can also produce large number of exosomes which are able to selectively detect their target tissues and bypass immune barriers. They can both suppress/promote tumor growth by different mechanisms which depend on several factors including cell source and content of exosome, target cells and interaction of exosome surface molecules with tumor cells. The bioengineering of stem cells changes gene expression pattern of placenta-derived MSCs and improves their antitumor effects. Both viral and non-viral vectors could potentially be used which are still under investigation for their efficacy on gene transduction and transmission of viral infections [2, 3].

CONCLUSIONS: Overall, it seems that incorporation of antitumor drugs with placenta-derived MSCs may be of potential therapeutic value for cancer which exert both selectivity and efficacy in tumor suppression.

How ex vivo vascular human-based models can give new insights in the study of vascular diseases

Current methodologies to study vascular diseases at a supra-cellular level mainly involve animal models. In line with the 3Rs spirit, we developed several ex vivo culture systems hosting human-derived vascular tissue. We conceived simple and easy-to-use culture chambers - consisting of ad-hoc-developed chassis integrated into conventional lab equipment - for hosting native or engineered vessels coupled with control and fluidic systems enabling realistic and dynamic culture conditions. This approach allows the investigation of human tissue maladaptation in a tightly controlled environment.

CYCLIC PRESSURE CULTURE SYSTEM: This model is designed to apply a cyclic pressure stimulus (e.g., 80-120 mmHg), within a controlled environment. We used this system to investigate the effects of strain wall mechanical stimulus on native vessels such as human saphenous veins (hSV) [1], [2], and to enhance the maturation of engineered constructs [3], [4].

CORONARY HEMODYNAMIC SYSTEM: A compact, modular, and low-priming-volume pulsatile simulator was designed enabling stimulating hSVs under realistic coronary artery bypass graft (CABG, Q\text{mean} 150-170ml/min, P 80-120 mmHg) and venous perfusion (VP, 5 mmHg; 3 ml/min) conditions. Our results [5] revealed i) decrease of the intima and media thickness in CABG, ii) presence of endothelial cells (ECs, CD31 and vWF markers) in the luminal side with partial endothelial denudation, and iii) cell apoptosis in CABG. Recently, this system is being used to study the role of trombospondin-1 (TSP-1) in CABG-stimulated hSV, investigating the possible strain-dependent activation of adventitial resident progenitors by TPS-1.

DOUBLE-COMPARTMENT CULTURE SYSTEMS: They are designed to reproduce differential environments in luminal and adventitial sites. We developed two different culture chambers: i) a falcon-tube layout, that we used to investigate oxygen gradients effects on hSV [6] and ii) a new low-priming Petri-like 3D-printed system that we use to reproduce a reliable vascular thrombus ex vivo model. Our experience shows that using bioengineering approaches facilitates the understanding of vascular physio-pathological mechanisms and, in perspective, will speed up the development of new-lifesaving treatments.

INTRODUCTION: In this study, we demonstrate new microfluidic methods of precise, reproducible production of compact 3D structures from hydrogel microbeads. We use microfluidics both to formulate hydrogel microbeads as well as to reaggregate them into small close-packed agglomerates of well-defined topology. We propose that such advanced topological structures could be used as new 3D culture scaffolds in which cells get segregated in separate microcompartments to reproduce the morphology and functionality of actual tissues.

METHODS: To prepare the microbeads, the hydrogel solution and a cross-linking initiating enzyme were injected at two independent inlets into a PDMS-based microfluidic chip. The two streams merged before entering a T-junction where the solution was turned into droplets carried by fluorinated oil with surfactant as the external phase. After washing out the surfactant, the beads agglomerated and could be easily translated into buffer. After filtering, the suspension was reinjected onto microfluidic chip with gradually narrowing and shallowing channel, designed in order to avoid clogging, terminating at a T-junction for re-encapsulation of the beads into hydrogel shells.

RESULTS & DISCUSSION: Depending on the applied flow rates, we were able to encapsulate from N=2 up to N=12 gelatin beads-cores in a single gelatin shell. The structures had reproducible, predictable topology following the topologies observed earlier for colloidal clusters or in double-emulsion droplets with multiple cores. We also managed to reproducibly encapsulate given numbers of different core types (labelled with TRITC vs FITC). In order to demonstrate suitability for cell encapsulation, we generated simple cell-laden beads (C2C12, fibroblasts, HUVEC) as well as co-encapsulated beads loaded with cancer cells, HUVECs and/or fibroblasts into agglomerates for topological 3D co-culture studies. We found that the re-encapsulation method is suitable to any kind of enzymatically cross-linkable hydrogel, i.e., also to fibrin, typically applied as extracellular matrix substitute, e.g., in angiogenic assays.

CONCLUSIONS: This study provides new type of hydrogel microparticles built of several compartments arranged in well-defined close-packed topology. Such particles allow for formation of microtissues with direct cell-cell communication and predesigned spatial arrangement. We are currently investigating suitability of such platform to co-culturing tumor cells with ECs and fibroblasts with the ultimate goal of mimicking cancer microenvironment for studying drug efficacy and tumor development.
PHLDA3 overexpression in astrocytes causes endoplasmic reticulum stress
M. Řehořová1,2, J. Turečková1, I. Vargová1,2, J. C. F. Kwok1,3, J. W. Fawcett1,4, P. Jendelova1,2

INTRODUCTION: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease with a fatal outcome characterized by the loss of spinal cord and brain motor neurons (MNs), which control voluntary muscles. Previous studies have shown that astrocytes (ACs) contribute to MNs degeneration and death in ALS. However, the mechanisms underlying the behavioral change of ACs during the pathogenesis of ALS remain unclear. Recent evidence suggests that pleckstrin homology-like domain, family A, member-3 (PHLDA3) could participate in astrocyte-specific degeneration process in ALS. PHLDA3 was shown to be significantly upregulated in the ACs in ALS. In additional, PHLDA3 was recently discovered as a molecule implicated in p53-dependent signaling and is activated in endoplasmic reticulum stress (ER stress). ER stress is one of the mechanisms implicated in the pathogenesis of ALS. The aim of this study is investigating the role of PHLDA3 in the interaction of MNs and ACs during activation of ER stress in ALS in vitro model.

METHODS: In this study, we used an optimized isolation protocols suitable for ACs isolation from the cortex of mouse pups of postnatal day 1-3 (P1-P3) and MNs derived from embryonic day 14 mouse spinal cord. The functional effect of PHLDA3 on primary ACs cultures was demonstrated using plasmid delivery of PHLDA3 gene fused with a green fluorescent protein (GFP). The expression of PHLDA3, marker of ER stress (p-eIF2alpha) and p53 were evaluated using Western blot and fluorescence microscopy. To test that PHLDA3 overexpression in ACs may cause astrocyte-mediated toxicity to MNs, we cultivated MNs with conditioned medium collected from ACs overexpressing PHLDA3.

RESULTS & DISCUSSION: We demonstrated that overexpression of PHLDA3 resulted in an increased level of p-eIF2 alpha and decreased survival of transfected ACs, while overexpression of PHLDA3 directly in motor neurons had no effect on activation of ER stress.

CONCLUSIONS: Our results suggest that overexpression of PHLDA3 in astrocytes causes their death by ER stress and the modulation of PHLDA3 expression may be exploited in designing new strategies to control astrocytic death in ALS disease.

INTRODUCTION: Mesenchymal stem/stromal cells (MSCs) present tremendous potential for cell-mediated therapy in many disease processes such as osteoarthritis (OA). However, one of the major challenges to clinical translation is a lack of understanding about engraftment of delivered cells in a tissue and their biological activity in situ. STARSTEM is an EU horizon 2020 project that aims to develop a novel nanotechnology-enhanced optoacoustic imaging (OAI) platform. The core novelty of this approach is a gold nanoparticle, shaped like a star (the nanostar), which amplifies signal response in OAI. The STARSTEM platform will be capable of tracking MSCs and MSC-derived exosomes, labelled with nanostars, at unprecedented depth and sensitivity.

METHODS: Development of the STARSTEM technology begins with optimization of the nanostar production process to allow generation of high-quality, nanostars capable of being produced under GMP conditions. MSC and MSC-derived exosomes will then be tagged with nanostars and assessed for viability. Nanostar-loaded MSCs will then be deployed in a mouse model of OA and tracked over time using OAI. This will then be extended to a large animal (ovine) model of OA as the selected pre-clinical model. Data generated will support an application for a phase-1 clinical trial of nanostar-enhanced OAI in humans. The development of the STARSTEM technology has included quality control analysis of nanostars and their effect on MSCs. Transmission electron microscopy has provided morphometric analysis of the nanostars. Nanostar-loaded MSCs have been assessed in terms of cell viability, tri-lineage differentiation capacity and cell surface marker expression.

RESULTS & DISCUSSION: Dark field imaging has shown the uptake of nanostars by MSCs. These nanostar loaded MSCs showed no reduction in cell viability or metabolic activity. Their cell surface marker profile was compliant with ISCT standards. Differences in the differentiation potential between control and nanostar loaded cells was observed, however. Nanostar-loaded MSCs showed a promotion of osteogenesis and chondrogenesis, the possible basis for which is currently being investigated.

CONCLUSIONS: In conclusion, the STARSTEM technology will lead to improved tracking of MSCs, and thus a better understanding of their mechanism of action, engraftment and biodistribution in disease models.

INTRODUCTION: Organ preservation plays an important role in a successful transplantation. Various surgical methods for organ transplantation have been explored throughout the years, each of which possesses its own advantages and disadvantages. To investigate the excellent methods, we made a comparison of different effects in more widely utilized methods of organ preservation and transplantation surgery in a variety of animal models. To do so, we assessed the function of the organ by specific enzymes, necrotizing factors and ischemia after hours of preservation in the transplanted organ.

METHODS: The searched keywords were “organ transplantation”, “animal models”, “Large animal” and “small animal”. Main databases used included “PubMed” and “Google scholar”.

RESULTS & DISCUSSION: The results depend on the organ used in transplantation and size of the animal model. Each organ has its own characteristics that require distinct methods to evaluate cold storage solution in the transplantation process. Temperature changes, whether hypothermia or normothermia affect the reperfusion of organ grafts [1]. Moreover, cytotoxic anticoagulants for preventing microvascular thrombosis can reduce reperfusion-related ischemia.[2] Biliary complications are almost inescapable specially in small animals such as rats, mice and rabbits.[3] This results in a vast preference towards using larger animal models for transplantation surgery. These animals include Canine, Porcine and Primate models.

CONCLUSIONS: It is important to find the optimal way for organ preservation and methods of surgery in animal models to reduce the injury and to maximize the function of the transplanted organ. We presented different methods with a variety of functional and mechanical changes in the transplanted organ after a long duration of preservative process.

INTRODUCTION: There are a lot of studies on decellularized tissues and organs due to their great capacity to use as a substitute for organ donation and transplantation; However, angiogenesis and how to supply oxygen and nutrients for cells remain the decisive challenge in acellularized tissue application. We presented here the recent advances regarding the factors impacting angiogenesis in decellularized tissue and organs.

METHODS: Literature search was done by searching “prevascularization”, “Re-endothelialization”, “endothelial differentiation”, “angiogenesis inducer”, “vasculogenesis” and “optimized acellularization” keywords in Pubmed and Google scholar published within the last ten years.

RESULTS & DISCUSSION: Several strategies have been hired to induce in-vivo and in-vitro angiogenesis including re-endothelialization, prevascularization, endothelial differentiation, endothelial culture and cell coating [2]. Scaffold specification is another key matter that influences induction of angiogenesis [3], but what these specifications are and how to optimize them [1] is yet some essential questions that need to be answered in the future studies.

CONCLUSIONS: The current angiogenesis inducing protocols have provided evidence of notable progresses, while there are important challenges needed to deal with.

ACKNOWLEDGEMENTS: Research reported in this publication was supported by Researcher Grant Committee under award number [963951] from the National Institutes for Medical Research Development (NIMAD), Tehran, Iran. We would like to thank Dr. T. Tayebi and Dr. B. Nooshin for their many assists.

INTRODUCTION: The scaffold component of tissue engineering is key to achieve tissue regeneration as it provides a 3D environment for cells to build new functional tissue. A vital part of the regenerative process in various tissues such as skin or bone is formation of a vascular network for delivery of oxygen/nutrients and removal of metabolites. Chorioallantoic membrane (CAM) of chicken embryos have been used as a model to study angiogenesis in ovo for nearly 20 years¹. Whether or not it could be used as proof of concept for scaffold testing is currently unknown. We used the ex ovo CAM assay to substantiate whether structure or composition of a scaffold could influence its angiogenic properties and therefore, determine the feasibility and accuracy of this method for scaffold testing.

METHODS: Fertile chicken eggs were incubated for 3 days after which, embryos were transferred to shell-less culture system under sterile conditions. A range of commercially available and pre-clinical scaffolds for skin and bone were applied to the developing CAMs at day 6 post ex ovo. The scaffolds tested included but were not limited to Integra®, Matriderm®, demineralized bone matrix (DBM) and polycaprolactone (PCL). Controls were filter discs soaked in VEGF and PBS. From day 9 to day 12, angiogenesis was examined macroscopically. At day 12, embryos were sacrificed ethically and angiogenesis in stereomicroscope images of different scaffolds was quantified using ImageJ software. Histological processing and staining was also carried out.

RESULTS & DISCUSSION: There was a clear trend between porosity and the degree of angiogenesis, where more porous scaffolds showed a higher percentage of vascular area relative to the size of the scaffold. This was also dependent on the composition of the scaffold for e.g., a more porous scaffold made of less angiogenic material like PCL was not as angiogenic as a similarly porous scaffold made of fibrin, which is pro-angiogenic. The data suggests that there is a fine balance between structure and composition that can positively or negatively influence angiogenesis.

CONCLUSIONS: Our data suggests that CAM assays can be used as a proof of concept for scaffold testing prior to in vivo animal testing. This ex ovo method is safe and inexpensive compared to the currently used methods such as Matrigel assays or ELISAs which are complex and are far from mimicking the in vivo situation. In the light of the principles of reducing animals for research (NC3Rs), we share the views of the authors who recently published a review in tissue engineering² suggesting that researchers should adopt this technique for scaffold testing. #

INTRODUCTION: Alzheimer disease (AD) is an age-dependent neurodegenerative disorder resulting in impairment of memory, speaking and practical habits. The AD is usually accompanied by neuroinflammation and the brains of AD patients are characterized by cholinergic deficiency and accumulation of extracellular senile plaques formed by oligomerized amyloid beta (Aβ) peptides. Mesenchymal stem cells (MSCs) are known to be the restoring agent for various damages including neurological. The aim of the present work was to study, whether inflammation-induced effect on the brain and behavior of mice can be reversed by human umbilical cord MSCs (hUC-MSCs).

METHODS: MSCs were obtained from Wharton jelly using the explant method. The cells of the second passage were intravenously transplanted into C57Bl/6 mice (10⁶ cells per mouse) three weeks after intraperitoneal LPS injection when memory decline was already observed. Mice were examined in memory test every week thereafter, then sacrificed and their brains and brain mitochondria were studied for the level of nicotinic acetylcholine receptors, Aβ(1-42), micro- and astroglia markers by ELISA and immunohistochemistry. Mitochondria sustainability to apoptogenic effect of Ca²⁺ was assessed in cytochrome c release assay.

RESULTS & DISCUSSION: hUC-MCS satisfied minimal criteria for defining multipotent mesenchymal stromal cells according to CD34, CD44, CD45, CD90, CD73, CD105 surface markers expression. MSCs restored memory of mice in 1 to 3 weeks after injection and significantly improved their brain mitochondria sustainability to Ca²⁺. This was accompanied by up-regulation of nicotinic acetylcholine receptors α4, α7, α9, β2 and β4 subunits and decrease of Aβ(1-42) in the brain and brain mitochondria. Surprisingly, MSCs additionally activated astrocytes of LPS-treated mice.

CONCLUSIONS: Positive MSCs effect when pathological symptoms have already developed (MSCs injection three weeks after LPS) allows suggesting that MSCs, or their soluble factors, directly or indirectly (by activating glial cells) restore the activity of damaged brain neurons. Further experiments are needed to reveal whether the recovery observed under the MSCs effect is long-lasting or just temporal.

**INTRODUCTION:** Nanofibrous polymeric materials are well-known for providing local, sustained and prolonged delivery of therapeutic agents. Therefore, compared to conventional therapies, they prolong the therapeutic effect, reduce side effects and increase the drug compliance [1]. In ophthalmic applications they constitute a very promising and yet not deeply studied structure [2]. Nanofibers made of hydroxypropyl cellulose (HPC) with β-cyclodextrin (β-CD) complexes with anti-glaucoma hydrophobic active ingredient brinzolamide were formed using the electrospinning technique. They will be stabilized on the cornea by HPC’s mucoadhesive properties [3]. β-CD/brinzolamide complexes should be released from them as a whole, freeing the drug only in contact with the hydrophobic cornea. Here we present basic physicochemical properties of these nanofibers.

**METHODS:** Formation of β-CD/brinzolamide complexes was done and the complexation effectiveness was determined in a form of apparent stability constant (KS) and complexation efficiency (CE). Solutions of HPC, β-CD and brinzolamide in hexafluoroisopropanol (HFIP) of 3-5% w/w were electrospun. The process parameters were optimized. Morphology of the electrospun nanofibers was observed using scanning electron microscope (JEOL JSM-6010PLUS/LV). Wettability tests were carried out using Dataphysics OCA 15 goniometer. Water solubility test was performed. Photographs were made and videos were recorded, and weight loss over time was measured.

**RESULTS & DISCUSSION:** Complexation of β-CD with brinzolamide was effective. In all of the three-component nonwovens, nanofibers were randomly oriented and showed adequate morphology. Small beads on thin nanofibers and local thickening were present in some of the nonwovens. The nonwovens were hydrophilic, what should enhance their mucoadhesion. Weight loss studies have shown the possibility of progressive biodegradation of the carrier in the tear film environment.

**CONCLUSIONS:** Obtained data are highly favorable and show a great potential of HPC/β-CD/brinzolamide nanofibers in ophthalmic applications. Approaches that were made will serve as a base for further research on brinzolamide release from the obtained nanofibers. Fiber modification is planned by replacing HPC with HPC modified by thiolation. Research will be complemented by mucoadhesion studies.

**ACKNOWLEDGEMENTS:** Research was supported by the funds of the project CePT POIG.02.02.00-14-024/08/ and POWER Och!Dok.

Expression and activity of TRPA1 and TRPV1 in the intervertebral disc: association with inflammation and matrix remodeling

Presenting Author: Olga Krupkova, okrupkova@ethz.ch

1Institute for Biomechanics, ETH Zurich, Switzerland 2Department of Orthopaedic Surgery, Fukushima Medical University, Japan 3Department of Orthopaedics and Traumatology, University of Hong Kong, China 4Department of Pharmacology and Pharmacotherapy, University of Pecz, Hungary 5St. Anna Hospital, Lucerne, Switzerland 6Prodorso, Zurich, Switzerland, *contributed equally

INTRODUCTION: Transient receptor potential (TRP) channels have emerged as sensors and transducers of inflammatory pain, with a possible relevance in degenerative disc disease (DDD). The aim of this study was to test the expression and function of TRPA1 and TRPV1 in intervertebral disc (IVD) inflammation and extracellular matrix (ECM) homeostasis.

METHODS: Human lumbar degenerated discs were collected from patients undergoing spinal surgeries and either analyzed directly by RT-qPCR (n = 25) or used for primary cell cultures (n = 30). Cells were stimulated with cytokines (IL-1β, TNF-α) to mimic the inflammatory/catabolic shift in DDD. Gene expression of TRP channels, inflammation mediators and ECM genes was measured by RT-qPCR, protein release by ELISA. The agonist allylisothiocyanate (AITC) was used to activate these channels (confirmed by calcium flux assay). ECM structure of caudal motion segments from TRPA1 (n = 20) and TRPV1 (n = 15) wild-type (wt) and knock-out (KO) mice was visualized by FAST staining. Statistical analysis was performed in GraphPad Prism.

RESULTS & DISCUSSION: TRPA1 and TRPV1 were expressed in 16% and 100% of degenerated lumbar discs, respectively. Cytokine treatment significantly induced gene expression of TRPA1 and reduced TRPV1 in disc cells. Experiments with AITC revealed that activation of TRPA1 (not TRPV1) reduced gene expression of ADAMTS5 and Collagen I. When compared with wt mice, mature TRPA1 KO mice showed signs of degeneration in the nucleus pulposus and the vertebral growth plate, while these tissues were unaffected in TRPV1 KO mice.

CONCLUSIONS: Our results indicate that TRPA1 may be involved in matrix remodeling and homeostasis during maturation and inflammation of the IVD. Follow-up studies are needed to fully elucidate the role of TRPA1 and TRPV1 in DDD.

ACKNOWLEDGEMENTS: Financial support was received from SNF, Eurospine and University of Pecs (EFOP-3.6.2-16-2017-0006 and GINOP-2.3.2-15-2016-00048).
Hyperacute serum therapy: the evaluation of regenerative potential in osteoarthritis treatment - In-vitro and in-vivo study

INTRODUCTION: Blood derivatives are becoming the first choice for injectables in the treatment of osteoarthritis (OA). The cytokine milieu of the joint is affected by the injection and may reflect the stage of the disease and any potential improvements. To identify the most beneficial treatment strategy for OA with the use of blood products, we established a 3D cell culture model of osteoarthritic chondrocytes. We investigated the interplay in cytokine composition between hyperacute serum and the osteoarthritic knee in human joint tissue explants and in a clinical investigation.

METHODS: PRP was generated by two centrifugation steps whereas hyperacute serum was produced using the hypACT auto device according to the manufacturer’s instructions. We analyzed the growth factor and inflammatory cytokine content of PRP and hyperacute serum. We established a 3D pellet culture model with OA chondrocytes, where we evaluated the therapeutic efficacy of PRP and hyperacute serum in osteoarthritis by histology, histochemistry and specific gene expression. The role of hyperacute serum in an inflamed environment was assessed with the co-culture explants model and a first-in man clinical study. Surgically excised knee tissues were activated by IL-1β and co-cultured with or without hyperacute serum. Patients with knee osteoarthritis (n=26) received 3 weekly injections of autologous hyperacute serum. Synovial fluid was harvested before each injection and clinical monitoring was followed up at 3 and 6 months. Forty OA-related cytokines were quantified by multiplex immunoassays in the culture supernatants and the synovial fluid.

RESULTS & DISCUSSION: The results from 3D cell culture model with the use of PRP and hyperacute serum in OA treatment revealed that hyperacute serum is a more effective blood product with a potential use in OA therapy. Hyperacute serum contains less inflammatory cytokines than PRP and enhances the expression of specific chondrogenic markers. Therefore we performed more thorough analysis of the hyperacute serum role on the cytokine milieu of the osteoarthritic joint. We identified that hyperacute serum decreased osteo- and rheumatoid arthritis markers in vitro and provided symptomatic relief in vivo. The cytokine pattern revealed that there are at least three different types of OA knees which probably have different underlying pathologies.

CONCLUSIONS: Hyperacute serum preserved viability of bone, synovium and cartilage and decreased the pro-inflammatory cytokine levels in vitro.

ACKNOWLEDGEMENTS: The authors are thankful for OrthoSera GmbH for the research support to Semmelweis and Danube Universities.
Surface functionalization of polyesters nanofibers via aminolysis and gelatin immobilization
O. Jeznach¹, D. Kolbuk¹, P. Sajkiewicz¹

Presenting Author: Oliwia Jeznach, oliwia.jeznach@gmail.com
¹Laboratory of Polymers and Biomaterials, Institute of Fundamental Technological Research, Polish Academy of Sciences, Warsaw, Poland

INTRODUCTION: The main limitation of polymer nanofiber scaffolds is associated with their hydrophobicity and the lack of biological cues on the surface, which hinder their effective interactions with cells [1]. Aminolysis combined with protein immobilization is one of the ways to enhance cellular response to polymer scaffold [2]. In this study, effectiveness of surface functionalization was compared for three types (polycaprolactone (PCL), polylactide (PLA) and poly(lactide-co-caprolactone) (PLCL)) of electrospun nanofibers.

METHODS: Three types of electrospun nanofibers were subjected to surface functionalization at the same conditions to compare effectiveness of process in the case of different polyesters. Firstly, samples were immersed in 6% w/v ethylenediamine /isopropanol solution at 30°C for 5 and 15 minutes to introduce free amino groups on the surface. Then, samples were activated with glutaraldehyde (1% w/v, RT, 2.5h). The last step was immobilization of gelatin on the surface using 0.2% w/v gelatin/water solution at 37°C for 20h. Samples were characterized by SEM observation, water contact angle measurements, quantification of amino groups and immobilized gelatin on the surface and mechanical testing. Also, L929 cells were cultured on the samples to evaluate biological response to modified scaffolds.

RESULTS & DISCUSSION: The applied process conditions did not change morphology of nanofibers. However, a decrease of Young modulus was observed for all samples, being the most significant for PLA samples. Prolongation of aminolysis time caused drop of stress at break in the case of PLCL and PLA samples. For all samples after gelatin immobilization surface became completely hydrophilic. After 5 days of culturing we observed well spreaded cells on the surface of modified samples in contrast to reference samples. The positive effect was visible even after first step of functionalization - aminolysis reaction, and increased with the time of aminolysis for PCL and PLCL nanofibers.

CONCLUSIONS: This study confirms that aminolysis combined with gelatin immobilization is effective method to enhance cellular response to polymer nanofiber scaffolds. Our study shows that effectiveness of process is different in the case of each type of polyester (the highest for PLA, and the lowest for PCL nanofibers), which has impact on amount of amino groups and gelatin on the surface as well as mechanical properties, but for all samples positive effect on cellular response was achieved.

The recent advances on the ingredients of cold storage solutions for liver transplantation

P. Parhizgar¹, T. Tayebi¹, A. Jafari¹, N. Halvaei¹, H. Niknejad¹

INTRODUCTION: The advancement of surgical techniques has strengthened hope in the liver transplantation as the final treatment of liver failure. However, there are obstacles in organ transplantation including the limitations in the number of transplant donors along with the occasional long distances between the transplant donor and receiver. This, in turn, lays the emphasis on the organ preservation methods so that the transplant tissue can be preserved with the least damage for a longer period before transplantation. In this study, we focused on the recent advances in static storage solutions and the effect of temperature on preserved tissue and organs.

METHODS: Articles in English were extracted through a comprehensive search in PubMed, Science Direct, and Google Scholar databases by the keywords “liver preservation”, “preservation solution”, “static cold preservation”, “ischemia-reperfusion”, and a variety of combinations of these words. The recent issue was defined as articles published from 2010 to the end of 2018.

RESULTS & DISCUSSION: The common current methods of organ preservation rely on the basis of preserving the tissue in storage solutions in a low-temperature media to minimize the damage to the tissue as well as to provide the tissue with energy supply [1]. Of the essential compartments of preservation solutions are electrolytes, free radical scavengers, and saccharides. At the time being, scientists are about to find ways to maximize the efficiency of preservation solutions for instance by the use of cell death inhibitors like Caspase-3/ Caspase-8 siRNA at a genetic and transcriptional level [2]. Furthermore, efforts are being made to reduce the adverse effects of temperature change on ischemia-reperfusion injuries.

CONCLUSIONS: Despite the efforts in optimizing the storage solutions, they are still not effective in preserving the liver for a longer period of time. Thus, further alterations must be implemented regarding cold storage solutions.

INTRODUCTION: Microfluidic technology is a powerful tool in biological and medical research because of offering the possibility of controlling samples in the microenvironment by down scaling. The traditional methods of cell culturing need high quantities of reagents and ingredient but these are reduced in this system [1]. Using microfluidic technology monodisperse cell laden microgel with tunable size can be generated making them useful building blocks that can be assembled into tissue constructs with spatially controlled physicochemical properties [2]. In this study we investigate recent advances in cell encapsulation hydrogels.

METHODS: The authors searched PubMed, Google Scholar, Scopus and other databases for keywords including “cell encapsulation”, “hydrogel”, “stem cells”, “microfluidic” and “Extracellular matrix” from 2012 to the end of 2018.

RESULTS & DISCUSSION: Processing capability and bioactivity are two important features of biomaterials used for cell microencapsulation. Only hydrogel materials have especial groups for crosslinking can be used. Alginate and alginate-based hydrogel have been used as main materials in cell encapsulation. However, there are some another appropriate materials that can be used for specific purpose. For instance, PEG is used for inducing secretory function in endocrine cells like beta pancreas cells with increasing survival rate of cells. Hyaluronic acid revealed specific properties related to angiogenesis and anti-inflammatory functions [3]. Chitosan is used for improving ionic gelation and it improves drug delivery. The crosslinking of hydrogels is a main determinant in cell encapsulation by microfluidic approach.

CONCLUSIONS: Hydrogels are of a very wide use in tissue engineering applications such as space filling agents or delivery vehicles for bioactive molecules. The most important characteristic of hydrogels is to have appropriate physiochemical properties to fit biological variants inherit to each application, for example having enough elasticity when working on uterus or having electrical conductance when working on neurons or myocardial cells or hypothermic preservation when working on adipose tissue.

ACKNOWLEDGEMENTS: The authors thank A. Ebadi for his assistance in this research. Research reported in this publication was supported by Researcher Grant Committee under award number [963951] from the National Institutes for Medical Research Development (NIMAD), Tehran, Iran.

Human dental pulp stem cell-derived extracellular vesicles stimulate the expression of microglial TREM2
P. Gervois1, M. Lo Monaco1, Y. Dillen1, T. Vangansewinkel1, R.B. Driesen1, G. Merckx1, H. Kemps1, A. Bronckaers1, E. Wolfis1 and I. Lambrechtis1

INTRODUCTION: Stroke is the second most common cause of death and is a major cause of permanent disability. Novel therapeutics aim to exploit the regenerative effect of stem cell-based therapies using for example dental pulp stem cells (DPSC). These therapies are believed to be mediated by paracrine factors including extracellular vesicles (EVs) that are produced by the transplanted cells and contain growth factors and (micro)RNAs. Microglia play an important role in balancing the inflammatory post-stroke microenvironment by obtaining a broadly defined pro-inflammatory M1 or pro-regenerative M2 phenotype thereby contributing to the exacerbation or alleviation of ischemic damage. One mechanism that is often overlooked in cell-based therapy is immunomodulation. In this study, the paracrine effect of DPSC factors on microglial polarization was evaluated. Moreover, triggering receptor expressed on myeloid cells 2 (TREM2) expression upon DPSC stimulation was assessed. TREM2 emerged as a novel target in stroke that is involved in phagocytosis and microglial function as TREM2 deficiency was detrimental for ischemic injury.

METHODS: DPSC-EVs were isolated by differential ultracentrifugation and evaluated with nanoparticle tracking analysis. In parallel, complete conditioned medium (CM) and EV-free CM of DPSCs was collected. Afterwards, volume-corrected EVs, full CM and EV-free CM was added to the mouse microglial BV-2 cell line. As controls for the pro- and anti-inflammatory M1 and M2 microglia phenotype, LPS and IL-4 were added to the cells respectively. Subsequently, the BV-2 phenotype was determined using NO measurements, qPCR and immunocytochemistry for TREM2. In another experiment, 24h after LPS stimulation, LPS, IL-4 and the CM fractions were added to the stimulated BV-2 cells in order to evaluate the ability of the DPSC-secretome fractions to counteract the M1 polarizing effect of LPS-induced NO production.

RESULTS & DISCUSSION: DPSC-EVs had an average particle size of 112.95 ± 9.75 nm (n=6). Neither fraction of the DPSC secretome induced an M1 response (n=6), based on NO production. However, no LPS-counteracting effect could be observed. No effect of DPSC-secretome components on Arg-1 and CD206 expression, both M2 markers, could be observed using qPCR. Remarkably, BV-2 cells significantly upregulated TREM2 expression following exposure to DPSC-EVs, but not when exposed to other stimulants (n=5, p-value < 0.01).

CONCLUSIONS: Exposure of BV-2 cells to DPSC-derived stimuli did not enhance their M2 phenotype. Interestingly, as TREM2 in stroke is associated with increased phagocytosis, the influence of DPSC-EV stimulation on the phagocytic capacity of BV-2 cells will be evaluated in future experiments.

A new role for the WNK1 kinase in corneal wound healing
P. Desjardins1,2, C. Couture1,2, L. Germain1,2, S. Guérin1
Presenting author: Pascale Desjardins, pascale.desjardins.1@ulaval.ca

INTRODUCTION: Damage to the corneal epithelium triggers important changes in the composition of the extracellular matrix (ECM) to which the basal human corneal epithelial cells (hCECs) attach. These changes are perceived by integrins, a family of trans-membrane receptors that activate different intracellular signalling pathways, ultimately leading to re-epithelialization of the injured epithelium [1]. Our goal is to study the impact of the pharmacological inhibition/activation of specific signal transduction mediators on corneal wound healing using both monolayers of hCECs and human tissue-engineered corneas (hTECs) as in vitro models.

METHODS: hTECs were produced by the self-assembly approach and wounded with a 8-mm biopsy punch whereas hCECs grown as monolayers were wounded using scratch assays (n=4). Total RNA and proteins were isolated from the wounded and unwounded tissues to conduct gene profiling analyses and protein kinase arrays. The wounded tissues were then incubated with the WNK1 inhibitor WNK463, the WNK1 agonist AM1241 [2], or with the vehicle alone (DMSO; negative control) and wound healing was monitored for up to 6 days (n=4).

RESULTS & DISCUSSION: Gene profiling analyses and protein kinases arrays revealed that expression and activity of several mediators from the integrin-dependent signalling pathways were altered in response to the ECM changes taking place during corneal wound healing. Phosphorylation of the WNK1 kinase turned out to be the most striking activation event occurring during wound healing. The pharmacological inhibition of WNK1 by WNK463 significantly reduced the rate of corneal wound closure in our hTECs (p=1.93E-07) and hCECs monolayers (p=2.58E-05) compared to their respective negative controls. It also reduced phosphorylation of the WNK1 downstream targets SPAK/OSR1 in wounded hTECs. Based on these results, we believe that the pharmacological activation of WNK1 could turn out to be an interesting avenue in order to speed up corneal wound closure, thereby reducing the risks of infection and their associated complications.

CONCLUSIONS: These results will contribute to a better understanding of the cellular and molecular mechanisms involved in corneal wound healing. Furthermore, they also identified a new function for the WNK1 kinase in corneal wound healing and might lead to the identification of a new therapeutic target in the field of corneal wounds.

INTRODUCTION: 3D Bioprinting technology has already made tremendous impact in the field of tissue engineering with bioprinted complex functional tissues with multiple cells. The translation of this technology to clinic requires however vascularization. Space programs in USA and EU have selected 3D Bioprinting as a future technology for “repair” of astronauts on long flights which are scheduled for example to Mars [1]. Microgravity and irradiation are two factors which might have big influence on success of 3D Bioprinting in Space [2]. Endothelial cells (ECs) which are major component of vascular system are for example highly sensitive to gravitational changes [3]. This collaborative study aims to investigate the effect of simulated microgravity on model 3D Bioprinted vascular tissue.

METHODS: Human Umbilical Vein Endothelial cells (HUVEC) from Promocell (cell density 8.3 x 10⁶ cells /ml) were mixed with universal bioink from CELLINK supplemented with fibrinogen at 5M cells/ml and then 3D bioprinted using a custom build extrusion based 3D bioprinter. Typical size of the bioprinted tissue constructs were 13.7 mm x 24 mm x 4 mm.

RESULTS & DISCUSSION: Constructs were printed with high fidelity. They were fitted in bioreactor from kiwi, AIRBUS and then exposed to microgravity simulator Gravite system at NASA KSC. Randomness is achieved when the rotational angle differs between the two axes and changes over time. There is a significant decrease in fluorescence intensity for nitric oxide (NO) from bioprinted samples kept in the microgravity simulator for 24 hours compared to control, suggesting vascular relaxation impairment. Results clearly demonstrated that the bioprinting process is not affecting the cellular production and consumption of NO, which supports the suitability of our model for researching pathophysiological imbalances in space.

CONCLUSIONS: This study demonstrates that 3D Bioprinting is suitable for biofabrication of viable large vascular constructs and simulated gravity had measurable effect on functionality.

ACKNOWLEDGEMENTS: The authors acknowledge NASA at KST, CELLINK AB, Sweden and AIRBUS for experimental support.

INTRODUCTION: Critical skin wounds are a major cost for the health sector and lead to immense suffering for the patients [1]. One way to facilitate healing of these wounds is through autologous adipose tissue transplants [2]. However, the implanted tissue needs to be vascularized or it will suffer from necrosis. To combat this, stromal vascular fraction (SVF), isolated from fat, could possibly be utilized. SVF has been shown to promote both vascularization and the wound healing process. In this project we evaluate a method which combines SVF with 3D Bioprinting to create thick fat grafts for in situ vascularization [3].

METHODS: Lipoaspirate was taken with consent from patients undergoing plastic surgery and adipose tissue was isolated with MiniStem devices, from JoinTechLabs, USA). Two MiniStem protocols were run: (i) fat was fractured and collected (ii) fat was enzymatically treated with collagenase. After the enzymatic treatment the SVF was collected and analyzed with FACS. Both fractions were mixed with a hydrogel composed of nanocellulose and alginate [4]. The resulting cell laden hydrogels (bioinks) were 3D bioprinted as gridded constructs (3D Bioprinter INKREDIBLE+, CELINK, Sweden). The properties of the bioinks and final constructs were evaluated from a rheological perspective using a rheometer and by printing constructs with various geometries.

RESULTS & DISCUSSION: FACS of the extracted SVF fractions showed the presence of adipose derived stem cells, pericytes, endothelial cells, and fibroblasts. Rheology testing revealed that the bioinks displayed shear thinning properties. The printing experiments showed that the mixed hydrogels were homogenous and printable. The printing fidelity was improved by adding more nanocellulose and alginate.

CONCLUSIONS: We have shown that we can isolate both fat and SVF from the same liposuction procedure. These results also show that fat and SVF isolated with the MiniStem and mixed with biopolymers contains relevant cells and possesses good printability.

Auxetic and composite scaffolds show potential for use in tissue engineering

INTRODUCTION: Some natural biological tissues display auxetic properties where upon stretching uniaxially they also expand laterally, becoming thicker which corresponds to a negative Poisson's ratio. A porous auxetic scaffold has the potential to mimic the properties of natural tissue. Here we investigate the mechanical properties of fabricated auxetic and composite scaffolds, and biological tissue using 3D digital image correlation (DIC).

METHODS: Unconverted scaffolds were fabricated from polyurethane using a previously developed technique using thermomechanical triaxial compression (Figure 1). Composite scaffolds were made using converted scaffolds which were filled with a thermoresponsive pNIPAM-Laponite ® hydrogel (1C10) (HG). The mechanical properties of the scaffolds were assessed by uniaxial tensile testing on an Instron 3367 and 3D DIC (LaVision Strainmaster). Biological tissue samples were also tested. Smooth muscle cells were suspended in HG at 4x10^6 cells/ml at 37ºC. The hydrogel was absorbed into the scaffold and set by lowering the temperature below 32ºC. Scaffolds were cultured under standard conditions for up to 6 weeks.

RESULTS & DISCUSSION: Auxetic scaffolds (converted) were successfully fabricated demonstrated by the gaining of a negative Poisson’s ratio when compared to the unconverted control. Composite scaffolds were not auxetic. Smooth muscle cells cultured within the composite scaffold were suspended in the pores, supported by the hydrogel. Biological tissue samples showed comparable strain distributions to that of the composite scaffold.

CONCLUSIONS: 3D DIC has shown that the composite scaffold maintains a similar Poisson’s ratio and strain values to that of the biological sample over the tested strain range. Therefore this scaffold could be used to recapitulate the natural physical environment of cells from this tissue when under load. Histology revealed smooth muscle cells dispersed throughout the entirety of composite scaffolds when cultured for 6 weeks

**INTRODUCTION:** Small diameter vascular grafts (VGs) require improved short- and long-term resistance to stenosis [1]. In this study we have investigated VGs produced from blends of polyurethane Tecoflex (PU-Tec) with gelatin (Gl) and bivalirudin (Bv) by electrospinning.

**METHODS:** Tubular VGs (2 mm diameter, 100 ± 20 um wall thickness) were produced from solution of 3% PU-Tec (w/v %) with 15% Gl and 1.5% Bv (w/w % to PU) in HFIP using the NF-103 electrospinning system. Scaffolds (~150 um) produced from the full composition and scaffolds with only one of the additives were used as controls. VGs were cross-linked by glutaraldehyde as described [2]. Platelet adhesion on the surface of VGs after contact with the platelet-rich blood plasma was investigated by SEM on JSM-6460 LV (Jeol). Cell viability and proliferation of HUVEC on the surface matrices were evaluated after 2 and 4 days of cell seeding using Alamar Blue® reagent. HUVEC cultivated on culture plastic were used as control. VGs (13-15 mm) were implanted in infrarenal position of rats abdominal aorta, their patency was studied by ultrasound tomography, followed by post explantational histological and immunohistochemical examination (1, 12 and 24 weeks). Expanded-PTFE grafts (2 mm diameter, Ecoflon) were used as control.

**RESULTS & DISCUSSION:** SEM demonstrated that presence of Bv in the electrospinning solution and cross-linking of the proteins by glutaraldehyde decreased platelet adhesion to the surface of VGs. HUVEC cells preferentially adhered to and proliferated on VGs containing both Gl and Bv as compared with VGs that contained only one of the additives. Treatment of VGs with glutaraldehyde further promoted proliferation of HUVEC cells on the scaffolds as seen on the 2 and 4 day of incubation as compared with the untreated VGs of the same composition. Data showed that VGs from PU-Tec+Gl+Bv demonstrate 94.5% patency with no signs of aneurysmal dilatation in a long-term study (e-PTFE VGs demonstrate only 66.6%). Intimal hyperplasia of PU-Tec-based VGs was lower than in e-PTFE VGs (31 and 59%, respectively). Histological examination demonstrated that after 3 and 6 months both types VGs were covered with a neointimal layer, which corresponded to the normal structure of the intima of blood vessels. Immunohistochemical study showed weak expression of collagen 4 and factor VIII in the newly formed intimal layer on the surface of electrospun VGs, 3 and 6 months later expression of these markers were detected in both types of VGs.

**CONCLUSIONS:** Tecoflex-based electrospun VGs with Gl and Bv showed higher patency in a short and long-term perspective as compared to e-PTFE VGs with less pronounced intimal hyperplasia and better ingrowth of host cells.

**ACKNOWLEDGEMENTS:** The study was supported by a grant from the Russian Science Foundation №17-75-30009.

INTRODUCTION: Drug-eluting 3D matrices allow controlling the state of surrounding cells [1], however to establish delicate management of drug effects a strict control of release kinetics in required. Herein, we studied drug release from 3D matrices produced by electrospinning (ES) and destined for covering of vascular stents.

METHODS: Tritium-labeled paclitaxel (3H-PTX) and diclofenac (3H-DF) were synthesized by thermoactivated tritium exchange. Matrices were obtained from solutions in 1,1,1,3,3,3-hexafluoroisopropanol (HFIP) containing PCL as basic polymer, PTX or DF as drug, human serum albumin (HSA) and DMSO as additives. Electrospun matrices (150–180 µm) were characterized by tensile strength, SEM, XPS, contact angle, water absorption, weight loss etc. Drug release was evaluated by radioactivity of supernatants after incubation of matrices for different time intervals (up to 27 days) in PBS or in human blood plasma (BP). To mimic medium exchange at each time point the supernatant was removed from the matrices and the incubation was continued in fresh PBS or BP until the next time point, when the same procedure was repeated. Radioactivity was measured by β-counting in “ULTIMA GOLD LTT” scintillator.

RESULTS & DISCUSSION: Preparations of 3H-DF and 3H-PTX were obtained with a specific radioactivity of ~0.9 and ~0.3 Ci/mM, correspondingly. Radiolabeled drugs were combined with unlabeled to reach doses ~89 and ~0.46 μg/cm² of DF and PTX. All matrices consisted of fibers varying in diameter from 0.13 to 0.56 µm with a tensile strength similar to previously published data and a hydrophobic surface (except from matrices with HSA). Release of DF and PTX in PBS was very close to previously published data, suggesting diffusion dependent release. Introduction of HSA in ES solution increased the DF release from 20 to 75% in PBS and from 50 to almost 80% in BP. Incubation of the matrices with BP increased the efficacy of drug release presumably by binding of the drug with serum biomolecules. Similar character of drug release was observed for PTX. Exchange of PBS or serum after every time point increased DF and PTX release; in BP drugs were fully eluted within 3-9 days. It should be noted that SEM did not demonstrate any changes in the matrix structure in these time intervals. So far as XPS demonstrated overrepresentation of PTX in the surface layer of the fibers, DMSO was introduced in the ES solution to facilitate drug deposition in the fibers. It was shown that matrices produced from ES solution with DMSO and HSA released no more than 60% of PTX after 27 days even under medium exchange conditions.

CONCLUSIONS: The data demonstrate the necessity to take into account the medium exchange conditions in living systems as well as properties of drug distribution in the fibers.

ACKNOWLEDGEMENTS: The study was supported by a grant from the Russian Science Foundation no. 18-15-00080.

INTRODUCTION: Articular cartilage (AC) has an arcade-like collagen fibre organisation, enabling it to withstand the high loads passing through joints [1]. Despite previous attempts to repair AC defects, recapitulation of the complex tissue architecture remains a clinical challenge. It has been shown that the use of aligned pores improves cell infiltration, differentiation and zonally-organised matrix deposition [2]. The objective of this study is to determine the effect of pore microarchitecture (orientation and size) in AC scaffolds for TE.

METHODS: Porcine AC was pepsin-solubilised and freeze-dried in different conditions to produce scaffolds (Φ5xh3mm) containing random or aligned pores. Pore size was tailored by an annealing step during freeze-drying. Pore morphology was characterised by electron microscopy (SEM). Compression testing (20% ε) was used to characterise stiffness. Scaffolds, seeded with bone marrow cells, were cultured for 28 days in chondro- (CM), osteogenic (OM) or expansion media (EM). Biochemical and histological analysis were used to determined DNA, glycosaminoglycan (alcian blue staining), collagen and calcium levels.

RESULTS & DISCUSSION: Scaffolds with aligned pores showed higher stiffness than random pores. In CM, the highest levels of sGAG and collagen deposition occurred in scaffolds with aligned pores. Conversely, the highest level of calcium deposition occurred in scaffolds with random pores. Increasing pore size did not affect scaffold stiffness but was found to accelerate cellular ingrowth and homogenous tissue deposition.

CONCLUSIONS: The study identified that pore structure can be used to augment the capacity of solubilised AC ECM to support or supress chondrogenesis. Aligned pores enable higher cell/nutrient infiltration which may support condensation prior to chondrogenesis of BMSCs. The higher stiffness associated with the aligned structure did not supress chondrogenesis, but rather enhanced it as evident from higher sGAG and lower mineralization levels, demonstrating its potential for AC tissue engineering.

INTRODUCTION: Steatotic livers are more susceptible to ischemia-reperfusion injury than healthy livers, resulting in a higher rate of primary nonfunction, early allograft dysfunction and post-transplant vascular and biliary complications. The goal of our study was to show that normothermic preservation (NP) can minimize preservation-related injury and maintain the organ function and viability.

METHODS: Experimental study with 10 Large-White pigs divided in a control group (healthy livers, n=5) and a steatotic group (animals were subjected to a steatotic diet for 5 weeks, n=5). The existence of pathologic steatosis was confirmed by biopsies performed in the first and second month after the introduction of steatotic diet. Following hepatectomy, livers were connected to the ARK ex vivo NP system developed by EBERS. The ARK system is formed by a portable preservation unit, which features peristaltic and infusion pumps, heating and oxygenation systems, sensors and a control unit; and a disposable closed circuit, where the organ and the perfusate are contained in sterile conditions. The organ was perfused through the portal vein (PV) and hepatic artery (HA) at physiological hemodynamic conditions with a perfusion solution composed by autologous blood of the donor animal, Ringer’s Lactate solution, cefotaxime, methylprednisolone, heparin, insulin, a parenteral nutrition solution, epoprostenol and sodium bicarbonate. Secreted bile was collected for analysis. 0h, 4h and 8h after connection of the organ to the NP system more than 30 variables of different types were monitored and compared: perfusion parameters (PV and HA flow rate and pressure, pH, bile production), biochemistry (AST, ALT, FA, GGT, urea, albumin, total bilirubin, Na+, K+, Cl−, glucose, lipemic/icteric/hemolytic index), histopathology (macro/microsteatosis, fibrosis, portal inflammatory infiltrate, neutrophils infiltrate, isolated hepatic necrosis, central confluent necrosis, subcapsular necrosis, cholestasis) and other (initial/final liver weight, warm ischemia time).

RESULTS & DISCUSSION: Compared to healthy livers, steatotic livers were perfused in an equally satisfactory manner (HA pressure, 95.3±18.7 vs 86.6±9.3 mmHg, p=NS; HS flow rate 15.9±1.5 vs 14.9±4.8 ml/min/100g, p=NS; PV pressure 20.5±5.2 vs 10.8±6.1, p<0.05; PV flow rate 54.3±8.7 vs 50.9±12.9, p=NS), did not show worse values of hepatic damage (AST 365.6±165.1 vs 437.2±299.8 UI/l, p=NS; ALT 21.4±8.3 vs 32±7.7 UI/l; p=NS), had a larger production of bile (146.6±77.7 vs 71.7±60.8 g; p<0.05) and the histopathological parameters did not show any significant alteration concerning fibrosis, infiltrate, necrosis and cholestasis.

CONCLUSIONS: Collectively, these data illustrate the capacity of the ARK system to preserve healthy and steatotic livers in NP conditions. Steatotic livers maintained a viable hepatic function during NP and their behavior under NP was not inferior to healthy livers. NP can contribute to decrease the number of steatotic livers discarded for transplantation, thus increasing the donor pool.

INTRODUCTION: A short period of isolated normothermic perfusion (NP) can be used to improve the condition of the kidney after periods of warm and cold ischemic injury. However, the restoration of the organ function during NP is conditioned by the composition of the perfusate. Herein, we have assessed the influence of the vasodilator selection in preservation and resuscitation experiments.

METHODS: Female pigs were terminated and kidneys were exposed and subjected to 30 min of warm ischemia before being flushed with Ringer’s lactate at 4°C. Kidneys were then either directly reperfused for 3 hours on the ARK ex vivo NP system developed by EBERS (preservation) or stored in ice for 24 hours with Custodiol HTK before the 3-hour NP (resuscitation). The ARK system is formed by a portable preservation unit, which features peristaltic and infusion pumps, heating and oxygenation systems, sensors and a control unit; and a disposable closed circuit, where the organ and the perfusate are contained in sterile conditions. Kidneys were perfused with a perfusion solution composed by Ringer lactate, 20% human albumin, red blood cells as oxygen carriers, creatinine and sodium bicarbonate. The perfusate was supplemented continuously with a nutrients solution, insulin and a vasodilator (180 ng/h alprostadil or 0.25 mg/h verapamil). Secreted urine was collected for analysis and the corresponding lost volume of perfusate was replaced in the circuit. Renal flow rate, mean arterial pressure, urine output, temperature, glucose concentration, hematocrit and oxygen saturation were recorded continuously. A blood gas analyzer was used to record parameters for acid–base homeostasis. Serum and urine samples were obtained hourly for biochemical analysis and wedge biopsies were taken after 3 h of reperfusion for histological analysis.

RESULTS & DISCUSSION: The ARK NP system was able to maintain physiological levels of temperature, mean arterial pressure and arterial oxygen saturation in all cases at during the 3-hour NP. Kidneys preserved with alprostadil exhibited stable flow rates during NP, whereas organs preserved with verapamil experienced increasing flow rates in time, which were significantly higher (p < 0.001) than those obtained (p > 0.05) with alprostadil. No significant difference (p > 0.05) was found between the preservation and resuscitation groups. Urine output was increased (p < 0.001) in the presence of alprostadil. Tissue damage parameters (GGT, LDH) showed stable parameters during NP perfusion and no significant difference (p > 0.05) was found between groups. Histological analysis showed no significant tissue damage in all groups.

CONCLUSIONS: Collectively, these data illustrate the capacity of the ARK system to preserve kidneys in NP conditions. Verapamil led to lower values of intrarenal resistance, which indicates a better renal function.

Cellular self-assembly into 3D microtissues enhances the angiogenic activity and functional neovascularization capacity of human cardiopoietic stem cells

INTRODUCTION: While cell therapy has been proposed as next-generation therapy to treat the diseased heart, current strategies display only limited clinical efficacy. To improve cellular retention, cellular self-assembly into 3D-microtissues (MTs) prior to transplantation has emerged as an encouraging alternative [1]. Importantly, 3D-MTs have also been reported to enhance the angiogenic activity and neovascularization potential of stem cells. Therefore, here using the chorioallantoic membrane (CAM) assay [2] we comprehensively evaluate the impact of cell format (single cells (SCs) versus 3D-MTs) on the angiogenic potential of human cardiopoietic stem cells [3], a promising second-generation cell type for cardiac repair.

METHODS: A commercially available biodegradable collagen scaffold (Optimaix™, Matricel) was seeded with either 3D-MTs or SCs of human cardiopoietic cells and placed onto the CAM of living chicken embryos. The scaffolds were analyzed for their perfusion capacity in vivo using magnetic resonance imaging (MRI) assessment which was then linked to a longitudinal histomorphometric ex vivo analysis comprising blood vessel density and characteristics such as shape and size.

RESULTS & DISCUSSION: Cellular self-assembly into 3D-MTs led to a significant increase (p < 0.001) of vessel density mainly driven by a higher number of neo-capillary formation. In contrast, SC-seeded scaffolds displayed a higher frequency of larger neo-vessels resulting in an overall 1.76-fold higher total vessel area (TVA). Importantly, despite that larger TVA in SC-seeded group, the mean perfusion capacity (MPC) was comparable between groups, therefore suggesting functional superiority together with an enhanced perfusion efficacy of the neo-vessels in 3D-MT-seeded scaffolds. This was further underlined by a 1.64-fold higher perfusion ratio when relating MPC to TVA.

CONCLUSIONS: Our study shows that cellular self-assembly of human cardiopoietic stem cells into 3D-MTs substantially enhances their overall angiogenic potential and their functional neovascularization capacity. Hence, the concept of 3D-MTs may be considered to increase the therapeutic efficacy of future cell therapy concepts.

INTRODUCTION: Bone tissue engineering demands for rapidly calcifying scaffolds, for example by adult stem cells differentiating towards the osteoblastic phenotype [1]. Moreover, they should be well vascularized in order to provide sufficient nutrients and oxygen, especially in critical size grafts. Natural bone is mainly composed of calcified collagen where the microenvironment affects stem cells’ fate and differentiation. The calcification capacity as well as the vascularization of collagen seeded with stem cells may depend on the cell format the cells are applied.

METHODS: Human adipose-derived stem cells (ASCs) were seeded on commercially available collagen scaffold (Optimaix™, Matricel) to study the calcification. The cells were either seeded as single cells (SCs) or as 3D-microtissues (MTs). Moreover, the scaffold was also soaked with the secretome of 3D-MTs and SCs, respectively, before on-plantation on the chorioallantoic membrane of the chicken embryo (CAM assay) for one week. MicroCT analysis of ex vivo samples was performed to assess micro-calcifications. Histological assessment included Van Kossa staining (extent of calcification), H&E (vascularization), among others.

RESULTS & DISCUSSION: There was not only a higher calcification in the case 3D-MTs were seeded onto Optimaix™ scaffolds compared to SCs, but also a higher tissue infiltration from the CAM surface into the collagen scaffold. In addition, vascularization was increased, with more vessels in 3D-MT-seeded scaffolds compared to SC-seeded ones.

CONCLUSIONS: Calcification capacity as well as vascularization are influenced by the cell format the seeded stem cells are applied. Three-dimensional MTs favor calcification and lead to a higher vessel density in collagen scaffolds planted onto the CAM assay. It may be worthwhile to apply stem cells as 3D-MTs in bone tissue engineering to promote two basic and important processes for functionally adequate bone grafts: calcification and vascularization.

INTRODUCTION: Bicomponent nonwovens consisting of two biodegradable polyesters were electrospun and subjected to investigations.

METHODS: Poly(glycerol sebacate) (PGS) was synthesized using equimolar ratio of glycerol and sebacic acid monomers. Two types of prepolymers were synthesized – one with relatively low degree of esterification (DE) (prepolymeric, Prep), and the other one with higher DE (semi-crosslinked, S-C). Next it was blended with poly(lactic acid) (PLA) in three ratios, and electrospun using hexafluoroisopropanole (HFIP) solvent. Subsequently nonwovens were cured at high temperature (135°C) within 3h - 48h, under vacuum in order to crosslink PGS. Electrospinning process was optimized at preliminary stage. PGS crosslinking conditions were selected on the basis of two meaningful publications about optimizing PGS properties [1, 2]. Materials were characterized and analyzed using various methods: scanning electron microscopy (SEM), differential scanning calorimetry (DSC), Fourier-transform infrared spectroscopy (FTIR).

RESULTS & DISCUSSION: Both morphology and structure differ much when comparing samples with various types of PGS, and with various content of PGS within nonwoven. Higher crosslinking degree should preferably enhance PGS elastic properties, however it does not seem to occur in case of bicomponent nonwovens. In addition, nonwovens with various content of PGS are not equally susceptible to crosslinking. The higher content of PGS, the longer time is required to achieve the same crosslinking degree.

CONCLUSIONS: Bicomponent, electrospun nonwovens may be promising but in the case of PLA-PGS system it seems to be difficult to take the full advantage of PGS elasticity.

INTRODUCTION: The reconstruction of breast after lumpectomy and radical mastectomy remains a challenge to reconstructive surgeons. Post mastectomy reconstruction of the breast has two major routes, one with synthetic implants and another one with autologous surgical reconstruction but, both strategies bid a substantial overture for reconstruction of the breast (1). However, a tissue engineering approach can serve as a clinical impetus to restore and replace the breast. The key question is whether post-implantation of a tissue-engineered scaffold with/without cells can regenerate the breast.

METHODS: We fabricated 3 different prototypes of breast scaffolds using natural polymers such as collagen, elastin and fibrin as these polymers are an integral part of the human breast’s ECM. Scaffolds were fabricated with custom developed methods. Material and material-cell characterisation were performed to understand physical and biological properties of the scaffolds. To study toxicology and biological response of the scaffolds, they were seeded with rat adipose derived stem cells (ADSC) and implanted in 14 SD rats. Output was measured by haematology, microscopy, μCT and immuno-histological analysis.

RESULTS & DISCUSSION: Scaffolds were able to mature over time with increased mechanical properties from day 1 (0.24kPa) to day 28 (9.25 kPa). Expression of adipogenic genes (CEBP and PPARG) had a 7.04-fold increase on day 7. Haematological results indicated that host immune reaction was elevated by day 7 but normalised by day 21. Gross observation showed that scaffolds were able to integrate with the native tissue, vascularise, and presence of the fat depot by day 28 was observed. Histological analysis showed expression of adipose markers PPARG and Caveolin-1.

CONCLUSIONS: developed breast scaffolds had an ideal pore size pattern for angiogenesis, flow of nutrients, cellular migration and microstructure which reflects on dynamic interaction between cells and ECM with integration with the native tissue without eliciting any toxicity. This addresses issues encountered by existing breast scaffolds and implants. Hence, these scaffolds demonstrate translation.

INTRODUCTION: Scaffold based 3D tumour models are considered to have better niche mimicking capability in comparison to 2D systems. This is attributed to their tunable mechanical properties, ability to provide structural integrity along with better cell- cell and cell-ECM interaction. Our lab has previously reported that poly urethane (PU) based scaffolds can be used as a robust 3D structure to develop a pancreatic cancer model using a single cell type. However, the tumour microenvironment is heterogeneous in nature and consists of different cell types along with matrix proteins, all contributing to tumour formation, cancer metastasis as well as its response and resistance to treatment. As a result, recent studies have been focused on the generation of multicellular tumour spheroids; however, no studies have been reported till date for scaffold-based model. The aim of our work is to develop, for the first time, a PU scaffold based, multi cellular, robust 3D pancreatic tumour model using pancreatic cancer, stellate and endothelial cells.

METHODS: PU scaffolds were prepared using Thermal Induced Phase Separation (TIPS) method. Absorption based surface modification of the scaffolds enabled coating with ECM proteins for enhancement of ECM mimicry [2]. Cells were seeded on to the scaffolds at a seeding density of 0.5x10^6 cells/ scaffold for mono cultures and 0.25x10^6 cells/scaffold, per cell type for the multi-culture systems. Long term culture was carried out within the scaffolds. Various in situ assays including cell viability, SEM, immunofluorescence assay etc. were carried out at specific time points throughout the culture.

RESULTS & DISCUSSION: Our data show that endothelial cells and stellate cells can proliferate on both coated and uncoated PU scaffolds for 4 weeks. Cell viability analysis also highlighted that endothelial cells preferred ECM protein coated scaffolds in comparison to uncoated ones, similar to the cancer cells. We also show the feasibility of long term co-culturing of pancreatic cancer, stellate and endothelial cells on both uncoated and coated PU scaffolds.

CONCLUSIONS: Our data show, for the first time, the feasibility of PU scaffolds to support a multicellular tumour growth along with the possibility for a robust ECM mimicry. We highlight the development of a robust, long term niche mimicking model system for relatively high throughput, personalized study and treatment of pancreatic cancer.

INTRODUCTION: Bacterial contamination of expanded polytetrafluoroethylene (ePTFE) membrane may be an indicator of the long-term success or failure of periodontal guided tissue regeneration (GTR) [1-2]. The purpose of this study was to investigate characteristic of the bacteria population involved in infection of periodontal GTR.

METHODS: Class II furcation defects were created in the first and second premolars of 2 beagle dogs. Space-providing ePTFE membranes were implanted to provide for GTR. The ePTFE membranes were retrieved 8 weeks after GTR for detecting the species and population of bacteria on alveolar bone by selective and non-selective culture.

RESULTS & DISCUSSION: Fusobacterium nucleatum, Actinobacillus actinomycetemcomitans, Black-pigmented bacterium, Actinomycete, and Streptococcus mutans were detected from alveolar bone covered with ePTFE membranes or alveolar bone where ePTFE membranes were lost. Alveolar bone covered with the ePTFE membranes showed higher population of Fusobacterium nucleatum and black-pigmented bacterium compared with alveolar bone where the ePTFE membranes were lost.

CONCLUSIONS: Our findings implied that implantation of ePTFE membrane may increase the risk of infection of periodontal pathogens.

ACKNOWLEDGEMENTS: This work was supported by grants from the National NaturalScience Foundation of China (Grant 81470753) and the Beijing Natural Science Foundation (Grant 7182061).

INTRODUCTION: Additive manufacturing technologies (AMTs) like digital light processing stereolithography (DLP-SLA) are emerging methods for scaffold preparation in patient-specific bone tissue engineering approaches. These methods are traditionally based on (meth)acrylate resins resulting in highly crosslinked materials, which often suffer from poor mechanical properties. Moreover, (meth)acrylates exhibit considerable cytotoxicity and resulting polymer networks degrade to unfavorable polyacids. We established novel vinyl ester (VE) monomer systems with considerably lower cytotoxicity and polyvinyl alcohol as favorable degradation product. Tailoring of these material systems promises a novel class of DLP-SLA-processable biomaterials with potential applications as scaffolds for in vivo bone tissue regeneration.

METHODS: VE-based systems were explored and compared to (meth)acrylate benchmark systems. Polymer network regulation by established thiol-ene chemistry approaches were employed to increase reactivity and resulting mechanical properties, especially toughness.[1] Further toughness improvement was attained by including newly synthesized VEs with spacers of variable molecular structures [2], and macromolecular reactive and non-reactive resin additives.[3] Monomer cytocompatibility was tested by in vitro tests with murine fibroblasts. Photoreactivity was examined via RT-NIR photorheology. (Thermo-)mechanical properties of the crosslinked materials were determined via dynamic mechanical thermal analysis (DMTA), tensile testing, and impact testing.

RESULTS & DISCUSSION: Thiol-ene chemistry proved to be a valuable tool to increase resin reactivity and to improve the mechanical performance of the photopolymers due to its inherent network-regulation capabilities. Alternative network-modification strategies further increased the toughness of the materials while still maintaining their 3D printability.

CONCLUSIONS: VE-based resin systems can be tailored towards tough 3D-printable scaffolds as screwable implants for bone tissue regeneration approaches with superior biocompatibility, and biodegradation behavior.

INTRODUCTION: Diffuse idiopathic skeletal hyperostosis (DISH) affects mostly mid-aged and elderly people. DISH is characterized by the formation of bone along the anterior spine. Further ossification of the outer intervertebral discs (IVD) can be observed [1]. However, the nucleus pulposus (NP) remains unaffected. We have recently shown, that the IVD cells are expressing BMP antagonists, which could lead to inhibition of bone formation for spinal fusion. In this study, we investigate the transcriptome of discs of the BMP pathway from DISH patients with traumatic or degenerative discs.

METHODS: Fresh DISH-IVDs and trauma or degenerated IVDs were obtained from patients undergoing spinal surgery (approved by the Ethics Committee of the Canton of Bern, CH). TGFβ BMP signaling pathway genes were compared by qPCR. IVDs of three DISH patients were tested against three control patients (same disc level and similar age). IVD of two donors could be separated in NP, annulus fibrosus (AF) and cartilaginous endplate (CEP), one donor was investigated without discriminated IVD tissue.

RESULTS & DISCUSSION: In six of the seven comparisons a mean up-regulation of Interleukin 6 (IL-6) was detected (mean ± SEM of all comparisons: 88.8 ± 79.4-fold in DISH-IVD compared to controls). Early Growth Response 2 (EGR2) and Insulin-like Growth Factor 1 (IGF1) were up-regulated in DISH-IVD donors (i.e., 20.5 ± 12.4-fold and 19.0 ± 19.5-fold, respectively). The two Growth and Differentiation Factors 5 and 6 (GDF5 and 6) were down-regulated in two of the three DISH-IVDs (i.e., -21.9 ± 16.2-fold and -8.2 ± 4.2-fold, respectively).

CONCLUSIONS: Most interestingly, the DISH-IVD cells showed a considerable change in IGF1 and IL-6. IGF1 was already determined as a serum marker for rheumatic diseases, such as DISH. These results are unexpected considering the fact that the ossification occurs in the neighboring ligaments and enthesis leaving the inner part of the IVD macroscopically unaffected.

ACKNOWLEDGEMENTS: Financial support was received from direct funds from the Clinical Trial Unit, Inselspital, Bern University Hospital, and by a grant of the Swiss Society of Orthopaedics and Traumatology to C. E. A.

3D bioprinting of hepatocytes co-culture systems – towards biofabrication of liver models
R. Abdelgaber, A. Lode, M. Gelinsky
Presenting Author: Rania Abdelgaber: rania.abdelgaber@tu-dresden.de
Centre for Translational Bone, Joint & Soft Tissue Res., Technische Universität Dresden, Germany

INTRODUCTION: 3D bioprinting has emerged as a tool to develop biomimetic constructs that resemble the native microenvironment of tissues. Thus, the behavior and function of printed cells in a 3D environment can be improved compared to in vitro 2D cultures. Aim of this study is to design a liver model mimicking in vivo microenvironment by fabrication of constructs based on cell laden hydrogels and to further characterize their biological response in terms of viability and liver specific functions. Core/shell 3D bioprinting has been utilized for the fabrication of tissue constructs with spatial compartmental distinction between core and shell phases with encapsulation of different cell types in each phase. In an attempt to further mimic in vivo hepatic microenvironment, hepatocytes were co-cultured with supporting fibroblasts in a core/shell fashion were the two cell types are in close proximity. Such co-cultures are known to maintain hepatocyte viability and enhance their functionality.

METHODS: For the fabrication of core/shell scaffolds, BioScaffold 3.1 (GeSiM mbH, Radeberg, Germany) was used. Human HepG2 hepatocyte-like cells were encapsulated and processed in 3% HP-LVM alginate/9% methyl cellulose/20% Matrigel (alg-MC-matrigel) hydrogels. After plotting, scaffolds were stabilized via Ca$^{2+}$-mediated crosslinking and were incubated in (DMEM) supplemented with FCS, penicillin and streptomycin for up to 4 weeks Those HepG2 containing constructs were analyzed for cell viability by live-dead staining (calcein AM/ethidium homodimer-1), for cytoskeletal morphology via confocal laser scanning fluorescence microscopy, and concerning liver specific functionality, albumin secretion and E-cadherin expression were investigated. To characterize the influence of fibroblasts co-culture on the functionality of hepatocytes, NIH-3T3 fibroblasts were encapsulated in the core with HepG2 cells encapsulated in the shell. 3D printed scaffolds were crosslinked and cultured in DMEM for 4 weeks. Viability of both cell types and functionality of the hepatocyte-like cells were assessed.

RESULTS & DISCUSSION: Using the alg-MC-matrigel bioink, volumetric 3D printed scaffolds were successfully fabricated. HepG2 cells showed survival rates of around 60% after 24 h of incubation in medium. In comparison to 2D cultures of HepG2, cells encapsulated in 3D printed constructs showed enhanced functionality concerning albumin secretion. In 2D cultures HepG2 which are epithelial-like in shape tend to grow in clusters. In case of the bioprinted constructs, cells started to grow in aggregates/clusters at day 7 especially around macropores of the scaffolds where oxygen and nutrients are abundant. These clusters where spheroidal in shape and exhibited a 3D structure adapted to the geometry of the scaffold. HepG2 cells printed in core/shell fashion with fibroblasts as supporting cells in the core showed enhanced albumin secretion & cadherin expression.

CONCLUSIONS: 3D bioprinting is a promising approach to fabricate liver models which mimic the functional characteristics better than 2D in vitro cell cultures. Functionality of hepatocyte-like cells was further improved by co-culture of hepatocytes with fibroblasts using core/shell bioprinting technology. Co-culturing hepatocytes with non-parenchymal cells (e.g. fibroblasts) maintained hepatocyte viability and function, whereas hepatocytes cultured alone lost their characteristics.

INTRODUCTION: Organized networks are common in nature, where cells can be found isotropically or anisotropically distributed [1]. While progress was achieved organizing cells in two-dimension (2-D), reported fabrication techniques for aligned networks in 3-D are limited [2]. Here, we describe the use of a biomimetic extra-cellular matrix system to engineer anisotropic in vitro neural models.

METHODS: Polymeric blends of methacrylated gelatin and gellan gum were varied. Crosslinking and freezing were used as a mechanism to tune pore orientation, pore size and mechanical properties. 3-D neural constructs were developed culturing primary neurons isolated from embryonic mouse cortex. Heterotypic cultures with endothelial cells were performed in a custom microfluidic device.

RESULTS & DISCUSSION: The degradation rate and mechanical properties were controlled by adjusting the ratio of the polymeric blend, while the 3-D anisotropic structure and its pore size were tuned by varying the temperature of the freezing step and guiding the crosslinking. The top-down fabricated oriented porous structures in a single step process resulted in pore sizes ranging from 18\textmu m to 376\textmu m overcoming the resolution of similar techniques and ranging the size of human neocortex columns. As a model system, neurons were injected in the 3-D oriented porous systems creating 3-D neural anisotropic constructs at a large millimeter scale, which has not been achieved before. Further, we also aligned primary neurons interfaced with endothelial cells under dynamic conditions controlled by a microfluidic platform designed for co-cultures as an organ-on-chip type model.

CONCLUSIONS: The presented system can potentially be used to model several tissues in vitro, especially anisotropic neural tissues characterized by aligned neurites outgrowing from primary neurons. Degradation and mechanical properties were tuned by material engineering techniques with a meaningful neuronal organization. Degenerative conditions in the brain result in degradation, regional stiffness changes, altered neuron networks morphology and ultimately neuronal function loss as observed during aging, and degenerative disorders.

REFERENCES
INTRODUCTION: Guided tissue regeneration in periodontal disease remains clinically unpredictable. A major limitation of employed resorbable materials is the inability to exert spatiotemporal control over the wound-healing process. Employed resorbable membranes show a fast rate of biodegradation. Degradation products also alter remineralization. Novel polymeric membranes were designed and created by electrospinning. Functionalization of the polymeric membranes through the incorporation of bioactive components (calcium, zinc, silicon) was performed to enhance their osteoconductive properties [1]. Doxycycline was also doped on tissues to account for antibacterial properties. The aim of this study was the surface characterization of novel matrices by means of bioactivity, nanomechanical properties and topography.

METHODS: Polymeric matrices were created and loaded with silicon, zinc, calcium and doxycycline. Doping efficacy was probed. To probe for membranes’ bioactivity, the method proposed by Kokubo (ISO 23317:2012). Nanomechanical properties mappings were conducted using a Hysitron Ti Premier nanoindenter equipped with nano-DMA III (quasistatic force setpoint $F_q=2 \mu N$, sinusoidal force of amplitude $F_A=0.10 \mu N$ and frequency $f=200$ Hz). Atomic Force microscopy was employed for topography analysis.

RESULTS & DISCUSSION: Bioactivity of tissues was demonstrated in all doped tissues, but it was drastically increased in the presence of silicon. Calcium and phosphorous nanocrystals were encountered at the EDX spectra on nanofibers surfaces. SiO$_2$ tissues doped with Zn or Dox attained the highest amount of calcium/phosphate deposits. Mechanical storage moduli of ion-doped tissues were within the range 10 to 15 GPa. Nanofibers were randomly distributed and their diameter was around 300 nm.

CONCLUSIONS: Silicon doping and zinc complexation on tissues facilitated phosphate groups binding and calcium attraction from media. Doxycycline is known to form chelates with metallic ions such as calcium ions. Mechanical storage moduli of tissues are similar to that of calcified trabecular bone (15 GPa) [2], values that highly differ from the storage modulus calculated for cross-linked collagen scaffolds (1GPa). This is important, as substrate stiffness can modify cell behavior, and cells may probe and respond to mechanics in fibrillar matrices [3]. Nanofibers diameter is similar to that of mineralized collagen fibers on trabecular bone. It may be concluded that silicon modified tissues doped with zinc or doxycycline are candidates to accomplish guided tissue regeneration in periodontal patients. In vivo research is needed to confirm the effectiveness.

INTRODUCTION: Hyaluronic acid hydrogels play an essential role in the fields of tissue engineering and regenerative medicine. In the present study, a solution of a photocrosslinkable coumarin-hyaluronan (HA) derivative [1] was applied to chondral lesions in the knee of mini-pigs, and its efficacy and safety for cartilage repair was assessed at 8 weeks.

METHODS: Standardized circular full-thickness chondral defects (Ø: 5 mm) were created in the trochlear groove of mini-pigs and treated by (1) debridement, (2) debridement and microfracture (MFX), (3-4) debridement, microfracture, and two different prototypes of photocrosslinkable coumarin-HA solutions (p30 and p40), which were activated for the in situ gelation through 5 min near-UV irradiation (365 nm). The osteochondral repair was assessed at 8 weeks postoperatively using established macroscopic, histological, immunohistochemical, and micro-computed tomography analyses [2]. For the histological evaluation, sections were stained with Safranin-O/Fast Green protocol. A total of 320 stained sections (8 sections per defect) were analyzed applying the complex cartilage repair score described by Sellers et al [3].

RESULTS & DISCUSSION: Semi-quantitative histological analysis of cartilage revealed a significantly better overall structure of the repair tissue upon treatment with coumarin-HA p30, compared to the other three treatment groups. Enhanced defect architecture and surface architecture were observed within the repair tissue of the MFX + coumarin-HA p30 group compared to MFX alone. Furthermore, improved new subchondral bone formation was seen in p30 treated defects, compared to MFX. No significant difference of all µ-CT parameters was detected among the four treatment groups. Compared with the normal osteochondral unit, all treatment methods induced a general attenuation of µ-CT parameters of the subchondral bone plate.

CONCLUSIONS: The collected data illustrates the beneficial effect of a new UV-photocrosslinked hyaluronan hydrogel on early cartilage repair at 8 weeks in vivo in a translational animal model.

INTRODUCTION: Osteoarthritis and focal cartilage defects in the knee occur frequently. With increasing life expectancy, the need for therapies other than knee replacement is growing. Since the intrinsic repair capacity of cartilage is limited, other ways to stimulate cartilage regeneration are being explored. Platelet-rich plasma (PRP) is a blood product containing high growth factor levels and can be used in versatile applications [1]. PRP can be injected intra-articularly for the treatment of knee osteoarthritis. Moreover, platelet lysate (PL) is used for the expansion of cells for cell therapy [2]. This study aims to investigate the potential of using PL to stimulate cartilage matrix production by chondrocytes in vitro. In addition, the potential of PRP as a 3D cell carrier is explored.

METHODS: PRP and PL were prepared from human blood and platelet enrichment in PRP was determined. Human chondrocyte monolayers were subjected to a range of PL concentrations for 7 days. Cell proliferation and morphology were assessed. Expression of chondrogenic genes was determined by RT-PCR. Next, chondrocytes were brought back into 3D culture and cartilage matrix production was assessed after 28 days. Outcomes were cartilage extracellular matrix (ECM) formation by biochemical assays (glycosaminoglycans (GAG), collagen, and DNA quantification), gene expression analyses and histology. Next, PL was used at 1% and 5% as a supplement for redifferentiation of chondrocytes in pellets with similar outcomes on cartilage ECM production. Finally, PRP was used to make chondrocyte-loaded 3D gels.

RESULTS & DISCUSSION: PL had a dose-dependent effect on chondrocyte proliferation, but expression of chondrogenic markers was decreased. When brought back into 3D pellet culture, GAG production after 28 days was significantly higher for chondrocytes that were expanded with 1% PL compared to controls. When used for redifferentiation of chondrocyte pellets, PL decreased GAG and collagen production. This was confirmed by (immuno)histochemistry. Finally, chondrocyte-containing PRP gels showed similar results in terms of low GAG and collagen production. Again, this was confirmed by histology.

CONCLUSIONS: Platelet lysate stimulates chondrocyte proliferation in 2D monolayer and cartilage ECM production in subsequent 3D pellet culture. However, this does not work for high levels of PL. Furthermore, PL and PRP are not suitable for redifferentiation of chondrocytes.

INTRODUCTION: Mesenchymal stem cells (MSCs) exposed to TNFα during chondrogenesis have a reduced differentiation capacity. However, when MSCs are stimulated with TNFα during expansion phase, they have an increased proliferation potential [1] and an increased short-term survival rate in vivo [2], suggesting a possible role of TNFα in priming MSCs to better survive in vivo. However, the effect of TNFα priming on chondrogenesis of MSCs is poorly investigated. The aim of this study was to investigate the effect of TNFα pretreatment on MSCs chondrogenesis, even under the presence of TNFα during differentiation.

METHODS: Human MSCs were obtained from bone marrow of patients undergoing a total hip replacement (N=10). MSCs were expanded with 1 ng/ml FGF2 and 0, 1, 10 or 50 ng/ml TNFα for 24 hrs or 5 days. Next, the MSCs were chondrogenically differentiated for 4 weeks by standard pellet culture containing 10 ng/ml TGFβ, in the presence or absence of 1 ng/ml TNFα. Gene expression analysis, GAG and DNA biochemical analysis and histology were performed at the end of the culture to assess chondrogenesis.

RESULTS & DISCUSSION: GAG/DNA analysis and histology (GAG and COL2) showed that MSCs expanded without TNFα had a reduced matrix production when they were exposed to TNFα during chondrogenesis. Interestingly, after chondrogenic differentiation in the presence of 1 ng/ml of TNFα, MSCs pre-cultured with 10 ng/ml or 50 ng/ml of TNFα for 5 days have an increased GAG and COL2 deposition compared to MSCs pre-cultured without TNFα (Figure 1), and 1.9-fold increase in GAG/DNA. No significant difference was observed after pretreatment for 24 hrs. These results indicate that TNFα pretreatment for 5 days primes the MSCs to deal with the presence of TNFα during chondrogenesis. Furthermore after differentiation without TNFα, we observed that MSCs pretreated with 50 ng/ml TNFα for 5 days also have an increased GAG content (1.8-fold increase) and an increased COL2A1, SOX9, ACAN expression. This suggests that 5 days pretreatment with TNFα increases the chondrogenic capacity of MSCs, regardless the presence of TNFα during chondrogenesis.

CONCLUSIONS: This study showed that TNFα pretreated MSCs have an increased chondrogenic capacity. Given the positive effect on chondrogenesis, TNFα pretreatment can be beneficial for MSC-based therapies to treat cartilage defects.

INTRODUCTION: Decellularization (DC) of native tissue is a method to generate 3D scaffolds for medical applications. DC however can affect the mechanical properties of tissue, with implications for cell behavior in vitro or in vivo. In this study, we decellularized blood vessels with different fluid application methods and observed effect on biomechanics and protein retention.

METHODS: Porcine vena cavae were decellularized with a previously optimized method, utilizing the detergents TritonX and TnBP as well as DNase. The veins were decellularized in following perfusion settings: (1) static, (2) agitation or (3) perfusion with different perfusion speeds. Blood vessels were analyzed for cell removal, cytotoxicity, extracellular matrix (ECM) protein retention and biomechanics.

RESULTS & DISCUSSION: DNA quantification and histological stainings showed that all perfusion conditions completely decellularized the veins. Glycosaminoglycans were less present following DC compared to the native tissue in all groups. In contrast, the adhesion proteins fibronectin and vitronectin were retained. Scanning electron microscopy analysis showed no obvious alterations of the extracellular matrix (ECM) of decellularized veins, except for the group perfused with the highest velocity, which showed signs of tearing, indicating damage to the ECM. A cytotoxicity assay showed no negative effects of decellularized tissue on cell viability, indicating sufficient removal of detergents. Biomechanical analysis showed that maximum tensile strength and burst pressure were not different between native and DC groups, but the perfusion-DC groups showed an increased elastic modulus, indicating a higher local stiffness with increased perfusion velocities.

CONCLUSIONS: In conclusion, our data indicates that perfusion-DC negatively affects blood vessel biomechanics while static or dynamic DC retains native biomechanical properties.

INTRODUCTION: The extracellular matrix (ECM) is the natural environment of cells and has the potential to guide cell proliferation and differentiation by ECM structure and composition. In this study, we investigated the potential of decellularized brain ECM to act as a scaffold for neuronal stem cells. For this purpose, we processed brain ECM into a hydrogel, characterized hydrogel properties and performed cell viability experiments.

METHODS: Porcine brains were decellularized using a sodium deoxycholate/TritonX based method, lyophilized and milled into a fine powder. The ECM powder was furthermore solubilized by pepsin degradation and neutralized with NaOH to form a hydrogel at 37°C. Different concentrations of hydrogel were tested for stiffness, water holding capacity, and clotting kinetics by live-image analysis. Furthermore, we tested the growth and viability of neuronal stem cells embedded within the brain ECM hydrogel.

RESULTS & DISCUSSION: Porcine brains could successfully be decellularized, as indicated by low DNA content (reduction of >90%) and the absence of visible nuclei in DAPI section or whole tissue staining. Different methods for generation of brain hydrogel were tested, of which pepsin-degradation showed to be the most reliable. Lyophilization following pepsin neutralization lead to an ECM powder which can easily be diluted in water in concentrations of >3 mg/mL to readily form a hydrogel at 37°C. Clotting kinetics showed that clotting process can be accelerated by concentration of ECM hydrogel as well as by salt concentration and temperature. Stiffness of ECM hydrogel at different concentrations showed to be linear increased with higher concentrations, as observed with dynamic rheometric analyzer. Furthermore, cultivation of stem cells within the ECM-hydrogel lead to high cell viability and alignment within 3 days.

CONCLUSIONS: In conclusion, our data indicates that the brain ECM can be utilized as a hydrogel for neuronal stem cell growth and proliferation. Furthermore, we showed that the properties of the hydrogel can be closely manipulated according to the experimental requirements by different concentrations of ECM and salts. Further experiments concerning the differentiation potential of ECM-hydrogel compared with MatriGel will be performed.

INTRODUCTION: BARX1, a member of the homeodomain family of transcription factors, plays crucial roles in the tooth development [1,2]. Our previous study found that BARX1 is highly expressed in dental tissue-derived mesenchymal stem cells (MSCs), suggesting a potential function in regulating the differentiation of dental tissue-derived MSCs for dentin formation or tissue regeneration [2,3]. In this study, we used MSCs from dental root apical papilla (SCAPs) to investigate the functions of BARX1.

METHODS: SCAPs were isolated, cultured, and identified as previously described [2,3]. We over-expressed of BARX1 in SCAPs by retroviruses infection. After selected by 2 ug/ml puromycin, the expressions of Barx1 were observed by western blot. The dentinogenic markers including DSPP and DMP1, and osteogenic marker-BSP were measured by real-time RT-PCR.

RESULTS & DISCUSSION: Western Blot result showed that BARX1 was ectopically expressed in SCAPs. The real-time RT-PCR results showed that over-expression of BARX1 down-regulated the mRNA expressions of BSP at 3 and 7 after osteogenic induction, and up-regulated DSPP at 0 and 3d and DMP1 at 0, 3, 7, and 21d at the mRNA level in SCAPs.

CONCLUSIONS: BARX1, a transcription factor expressed in mesenchyme of molar primordia, is involved in regulating tooth morphogenesis, plays a role in development of tooth and craniofacial mesenchyme originated from neural crest [1,2]. Our findings suggested that BARX1 was an enhancer of dentinogenic differentiation and inhibitor of osteogenic differentiation in SCAPs. This indicated that BARX1 may be a key regulator to control dentinogenic differentiation in MSCs.

INTRODUCTION: Revascularization of pulp canal after endodontic treatment attains to rescue teeth from mid-term extraction fate, and can be promoted by the injection of hydrogels containing adequate cues. Herein are explored the proangiogenic effect of platelet-origin mediators modulated release [1] or hyaluronan oligomers instructive cues [2] within hydrogels aiming endodontic regeneration.

METHODS: Hyaluronic acid (HA) hydrogels incorporating PL were produced by mixing 2% aldehyde-modified HA solution containing aldehyde-functionalized cellulose nanocrystals (CNCs) with 2% hydrazide- functionalized HA dissolved in human platelet lysate (PL). Were assessed the sprouting of human dental pulp cells (hDPCs) or DPCs/HUVECs 1:1 pellets encapsulated in the HA hydrogels, and the neovascularization in a chicken chorallantoic membrane (CAM) assay. Also, low (LMW) or high (HMW) molecular weight (6 kDa and 230 kDa; Lifecore) HA were immobilized over methacrylated gelatin hydrogels (GelMA) and the response of HUVECs in terms of viability and arrangement analyzed.

RESULTS & DISCUSSION: PL incorporation enhanced the sprouting of DPCs both in single and co-cultures (p>0.001). Moreover, the combined effect of PL and DPCs encapsulation promoted the ingrowth of vascularized tissue into the hydrogels. The immobilization of LMW-HA over GelMA hydrogels enhanced the metabolic activity and promoted the organization of HUVECs into capilar-like structures.

CONCLUSIONS: Our findings from in vitro studies show that both the incorporation of human-origin proangiogenic growth factors and the creation of instructive paths of HA oligomers within injectable hydrogels, might promote the revascularization required for endodontic regeneration.

INTRODUCTION: Glioma, a malignant brain tumor, has poor prognosis, as it diffuses into the surrounding normal brain tissue. Since this invasion mechanism is still unclear, it is important to investigate the control factor of glioma invasion. Recently, we have developed a three-dimensional (3D) culture model of glioma stem cells in a microfluidic device, and demonstrated that endothelial cells promoted 3D invasion of heterogeneous glioma cells populations [1]. There are increasing evidences that biomechanical stimuli, such as interstitial flow, play important roles in cancer cell invasion. Therefore, in the present study, we investigated the effect of interstitial flow on 3D invasion of glioma stem cells.

METHODS: Mouse glioma stem cells [2] were cultured in a microfluidic device, which was made of polydimethylsiloxane and a cover glass. There are two microchannels and the intervening gel scaffold which is a mixture of type I collagen gel and Matrigel. Medium reservoirs were connected to the microchannels and interstitial flow was generated by 5 mmH₂O across the gel scaffold. Media were changed every day. Cell invasion into the gel was observed by phase-contrast microscopy, and morphological features of invading cells were quantitatively analyzed. Immunofluorescence staining was performed to investigate the mechanism of flow-enhanced cell invasion and the stained samples were analyzed using a confocal microscope.

RESULTS & DISCUSSION: Glioma stem cells seeded in a microchannel attached to the surface of the gel scaffold, and invaded into the underlying gel. When the cells were cultured under interstitial flow in the channel-to-gel direction (forward, Figure 1), invasion distance increased compared to static culture. In contract, gel-to-channel (reverse) flow attenuated cell invasion compared to static culture. We also found that invading cells in the forward flow conditions formed characteristic protrusions. Immunofluorescence staining revealed that integrin β1 highly expressed at the protrusions. In addition, expression of FAK and phosphorylated Src was upregulated in the forward flow conditions.

CONCLUSIONS: Our results suggested that invasion activity of glioma stem cells was regulated by the direction of interstitial flow. The flow-enhanced invasion might be involved in integrin-mediated signaling pathways.

Different roles for MEK isotypes in ESWT signal response
S. Nebel¹, T. Machacek¹, H. Redl², D. Rüenzler¹
Presenting Author: Sabrina Nebel, nebel@technikum-wien.at
¹Faculty of Life Sciences, University of Applied Sciences Technikum Wien, Vienna, Austria ²Ludwig Boltzmann Institute for Experimental and Clinical Traumatology/AUVA Research Center, Vienna, Austria

INTRODUCTION: Extracorporeal shockwave therapy (ESWT) is known to improve wound healing by activation of the ERK-cascade, which is linked to proliferation, differentiation and survival [1]. Recent findings showed that the upstream activators of ERK, MEK1 and MEK2, although highly similar, are not functionally redundant [2]. Herein, we investigated if the two MEK isotypes play different roles in the signal response to ESWT.

METHODS: MEK1 or MEK2 knockout (KO) cell lines were established by transfection (Metafectene Pro) of a pCAG-eCas9-GFP-U6-gRNA vector, expressing guide-sequences specific for either mek1 or mek2, into HEK293T cells, followed by clonal expansion. KO was confirmed by Western blotting and Sanger sequencing. 16 h prior to ESWT, cells were starved in medium containing 0.2% FCS to eliminate growth factor induced background signal. Established KO cell lines were harvested, adjusted to 10⁶ cells per 0.5 mL and treated with Dermagold ESWT-device (100 pulses; 0.19 mJ/mm²; 3 Hz). Protein was isolated 5 min afterwards for analysis of ERK and MEK activation via Western Blot.

RESULTS & DISCUSSION: Western Blot revealed multiple clonal cell lines with no detectable expression of the targeted MEK isotype (10 for mek1, 19 for mek2). Subsequent Sanger sequencing was used to verify a gene knockout and to analyze genomic sequence alterations. Premature stop codons on both alleles could be detected in two KO cell lines for both mek1 (B8, B10) and mek2 (KE2, JC9). Total protein expression of the remaining MEK isotype stayed unchanged. Treatment with extracorporeal shockwaves revealed significantly lower (p<0.0002) activation levels of total MEK (normalized to GAPDH) in MEK1 ablated cells compared to the control. Interestingly, this decrease did not reduce ERK activation levels. In cells lacking MEK2, similar levels of MEK as well as ERK phosphorylation could be detected, compared to wildtype cells.

CONCLUSIONS: Our data clearly indicate different roles of MEK1 and MEK2 in the signaling response to ESWT.

INTRODUCTION: Catechol-based systems provide novel properties such as adhesion, bioactivity and wettability modification [1,2]. Herein, we present the generation of a universally functionalizeable film in one-pot reaction which is especially attractive due to its potential versatility and ease of application.

METHODS: Thin free-standing films were synthesized in the air-liquid interphase by dissolving benzene-1,2-diol (10 mmol) and hexamethylenediamine (10 mmol). The films can be handled and deposited on different (bio)substrates. Additionally, the films can be functionalized with (bio)molecules of interest such as polyethylene glycol, folic acid and growth factors.

RESULTS & DISCUSSION: The catechol-based films were fully characterized by different techniques (FT-IR, XPS, UV-Vis, SEM). The thickness of the films can be controlled over the time achieving sizes from tens (77 ± 14 after 2 h of reaction) to hundreds (487 ± 16 nm after 48 h of reaction) nm. Once synthesized, the films can be easily transferred to different substrates allowing the modification of the surface properties. The tuneability of the reactivity of the films, lets the in situ and post-functionalization. Furthermore, the films are biocompatible and biodegradable in the cell culture.

CONCLUSIONS: A functionalizeable polydopamine-like film was successfully obtained by cross-linking polymerization of pyrocatechol with HMDA under oxidizing conditions. These results demonstrate the potential of the catechol-based films as a universal material that can act as a flexible platform for further functionalization with, for example, biomolecules of interest in biomaterials science, amongst others.

Combinatorial presentation of peptide sequences allows differentiation of mesenchymal stem cells towards distinct chondrogenic phenotypes
S. Camarero-Espinosa¹, J. Cooper-White¹,²
Presenting Author: Sandra Camarero-Espinosa, s.camarero-espinosa@maastrichtuniversity.nl
¹Australian Institute for Bioengineering and Nanotechnology (AIBN), Cnr College Rd & Cooper Rd, Building 75, Brisbane QLD 4072, Australia ²University of Queensland, School of Chemical Engineering, Brisbane, Qld, Australia

INTRODUCTION: Articular cartilage is a multi-zonal material in which chondrocytes assume different phenotypic states depending on the zone they are, i.e., persistent, proliferative and hypertrophic chondrocytes. These distinct chondrocytes deposit an extracellular matrix (ECM) that is specific to each of the zones and is responsible of the non-linear mechanical properties of the tissue. Tissue engineering strategies to regenerate cartilage have so far resulted on the formation of an isotropic neocartilage that lacks adequate differentiation status of the cells and insufficient mechanical properties.

METHODS: We hypothesized that mimicking the biochemical environment of cells in the different zones of cartilage will drive the differentiation of MSCs towards the distinct chondrogenic phenotypes. We performed a systematic study by presenting to human mesenchymal stem cells (hMSCs), varying ratios and concentrations of peptide sequences derived from the ECM (collagen I and IV and, decorin and heparin sulphate cell recognition sites) and cell adhesion molecules (E- and N-cadherin), and characteristic of bone and cartilage. After 2 and 3 weeks of culture, we analysed the ECM deposition and morphology of cultured cells by immunohistological experiments and the cell phenotype by polymerase chain reaction (PCR).

RESULTS & DISCUSSION: We used an adamantyl-modified block copolymer that readily self-assembles onto hexagonally packed nanodomains to conjugate peptide-modified β-cyclodextrin molecules on a controlled manner. Analysis of the phenotype and ECM deposition by MSCs differentiated on these substrates allowed us to understand the effect of the different peptides on cell morphology and organization (clustered vs spread), the role of the presented peptide density on cell organization and ECM deposition, and the optimal combination of peptides to differentiate hMSCs towards persistent, proliferative and hypertrophic chondrocytes.

CONCLUSIONS: We show that fine tuning chondrogenic differentiation of hMSCs is possible via the controlled presentation of spatial and chemical cues, deciphering the role of individual ECM-derived peptides in this process.

INTRODUCTION: Bioactive molecules are emerging as novel tools able to counteract different pathological cell conditions [1]. In particular, tannins and flavonoids, largely represented in the Mediterranean plant as Myrtus communis, are well known antioxidants [2], useful in counteracting aging and inflammation. Within this context, it has been shown that mesenchymal stem cells could be inhibited in their regeneration capabilities by an inflammatory microenvironment [3]. In the present work we evaluate the effects of Myrtus extracts, obtained from the waste of the liquor production, on stem cells behavior under stressing condition.

METHODS: Adipose derived stem cells (ADSCS) were exposed for 12-24 and 48h with 0,5 mg/ml extracts, derived from pulp berry and industrial waste, and then induced to senescence by H2O2 treatment. Were then evaluated ROS production, the expression of inflammatory cytokines and sirtuin-dependent epigenetic changes by real time RT-PCR, together with stemness related gene modifications. Finally, stem cell senescence was analyzed by the β-galactosidase assay.

RESULTS & DISCUSSION: Extracts exposure significantly decreased nitric oxide production and IL-6 expression, counteracting inflammation induced by oxidative stress. Real-time PCR analysis showed upregulation of pluripotency related genes (Oct4-Sox2 and Nanog) in cells cultured in presence of extracts compared with untreated cells. Moreover, after 48h of treatment, cells exhibited increased levels of HSP90 and SIRT1 activity, protecting cells from oxidative stress damages. These results were confirmed by β-galactosidase assay, which demonstrated that Myrtus products might counteract the premature senescence elicited by H2O2 treatment.

CONCLUSIONS: Industrial myrtle by-Products exert an anti-senescence and protective activity for the high contents of antioxidants molecules, still relevant even after the industrial utilization. Our results suggest a potential use of Myrtus extracts in modulating stem cell pluripotency and inflammatory response, to implement stem cell potential in regenerative medicine.

INTRODUCTION: Platelet rich fibrin is a blood concentrate system, gained by the centrifugation of patients’ own peripheral blood. The low speed centrifugation concept (LSCC) showed that reducing the applied centrifugal force (RCF) leads to significant improvement of the PRF bioactivity. The initial blood volume required to prepare PRF was 10 ml. The present study aimed to investigate the composition, regenerative capacity and therapeutic effect of PRF produced using 3 ml tubes to reduce the required initial blood volume.

METHODS: Peripheral blood was collected from 6 healthy volunteers after informed consent. 3 tubes of 10 ml served as control and 3 tubes of 3 ml were used in the test group. 3 centrifugation protocols according to LSCC were investigated (High-RCF: 710 xg; Low RCF: 177 xg and Medium RCF: 44 xg; all for 8 minutes). For each protocol 1 tube of 10 ml and 1 of 3 ml were centrifuged at the same time. The PRF bioactivity was evaluated using automated cell count for blood cells and quantification of growth factor (GF) release (PDGF-BB, EGF and TGF-ß1) for 7 days. The therapeutic effect of PRF was evaluated by cultivating primary human osteoblasts (hpOBs) using PRF-conditioned medium (PRF-CM) for 7 days. In this part, hpOBs cultured using DMEM+20%FCS served as appositive control. Cell proliferation and differentiation was measured on day 3 and 7.

RESULTS & DISCUSSION: in both test (3ml tubes) and control groups (10ml tubes) PRF matrices prepared using a high RCF contained significantly lower number of Platelets and leukocytes compared to those of low RCF. No statistically significant difference was observed in the number of platelets when comparing the test and the control group in the respective preparation protocol. However, the control group (10 ml, low RCF) contained statistically significantly higher number of leukocytes compared to the test group (3 ml, low RCF). PRF matrices of high or medium RCF released significantly lower GFs compared to those of low RCF. On day 5 and 7 statistically significantly higher TGF-ß1 concentrations were measured in the control group (10 ml tube, low RCF) compared to the test group (3ml tube, low RCF). However, EGF and PDGF-BB no statistically significant differences were measured at any time point. In both test and control groups, hpOBs that was cultured with PRF-CM of high or medium RCF showed statistically significantly lower proliferation compared to hPOBs cultured with PRF-CM of low RCF or DMEM+20%. No statistically significant differences were found between the test and the control groups. No statistically significant differences were found between PRF-CM (low RCF) and DMEM+20%FCS. Alizarin staining and quantification on day 7 showed that hpOBs cultured using PRF-CM of low RCF underwent statistically significantly higher differentiation compared to hpOBs cultured with PRF-CM of high, medium RCF or DMEM+20%FCS.

CONCLUSIONS: The present study proved that PRF-matrices produced using 3ml tubs show comparable bioactivity and therapeutic effect to those prepared using 10 ml tubes. PRF-CM showed comparable results to DMEM+20%FCS in the proliferation of hpOBs more positive effect in the differentiation. These data outline new perspectives for the use of PRF-CM in the in vitro cell culture research and minimal invasive PRF indication e.g. in pediatric regenerative medicine.
Characterization of extracellular matrix hydrogels from different tissues with the focus on neural tissue repair

INTRODUCTION: Extracellular matrix (ECM) hydrogels, prepared by tissue decellularization, represent natural injectable materials suitable for neural tissue repair [1]. However, it is not known whether tissue specific CNS-derived ECMs are advantageous for the neural tissue repair when compared to the ECMs derived from the other tissues.

METHODS: We compared ECM hydrogels derived from human umbilical cord (UC), porcine urinary bladder (UB), brain and spinal cord (SC) in terms of the composition, and mechanical and biological properties with the focus on neural tissue repair.

RESULTS & DISCUSSION: The ECM hydrogels did not differ from each other in the concentration of collagen, while the highest content of glycosaminoglycans (GAGs) was found for UC-ECM. In spite of a different GAGs content, all ECM hydrogels similarly promoted the migration of human mesenchymal stem cells (MSCs) and differentiation of neural stem cells, as well as adult dorsal root ganglion (DRG) axon growth in vitro [2]. We also did not find significant differences between the regenerative potential of UB-ECM and SC-ECM in vivo in the treatment of spinal cord injury [3]. However, the degradation of growth-inhibitory chondroitin sulfate proteoglycan by an enzyme chondroitinase ABC significantly improved in vitro DRG axon growth only in SC-ECM, but not in UC-ECM and UB-ECM hydrogels.

CONCLUSIONS: Based on these results, we propose that for the neural tissue repair, tissue specific ECMs derived from CNS, such as SC-ECM, might not be superior over the non-specific ECMs.

INTRODUCTION: Low back pain which restricts daily life activities and has a high incidence/prevalence is a major health problem. Damage or degeneration of intervertebral disc (IVD) which consists of an external annulus fibrosus (AF) and an internal nucleus pulposus (NP) is commonly considered as the main cause of low back pain [1].

METHODS: We developed a novel PCL microparticles with leaf-stacked structure throughout entire particles (ELSS) using PCL solution (in tetraglycol) by simple heating/cooling method, which can allow sustained release of growth factor for sufficient periods [2]. The release pattern of transforming growth factor-β3 (TGF-β3) from the ELSS and chondrogenic differentiation behavior of human mesenchymal stem cells (hBMSCs) by continuously released TGF-β3 were studied. To investigate whether the hBMSCs/TGF-β3/ELSS can provide appropriate environment for IVD regeneration, we used canine with IVD defects as animal models.

RESULTS & DISCUSSION: Prepared microparticles have unique leaf-stacked structure throughout entire particles (100-300 μm). It is observed that the TGF-β3 loaded in ELSS particles is continuously released for 18 days even without any specific and difficult immobilization. The TGF-β3-loaded ELSS particles provide suitable environment for chondrogenic differentiation of hBMSCs. hBMSCs/TGF-β3/ELSS group shows more enhanced IVD regeneration behavior than other groups at in vivo animal study using canine model.

CONCLUSIONS: Our findings suggest that our hBMSCs/TGF-β3/ELSS system may provide an appropriate environment for regeneration of damaged IVD, and thus a promising therapeutic tool to reduce pain and burden of patients with IVD disease.

INTRODUCTION: Insufficient oxygen supply to cells in tissue-engineered three-dimensional (3D) scaffolds may be the result of limited oxygen diffusion and/or slow ingrowth of blood vessels; this low oxygen environment (hypoxia) poses the biggest challenge to producing clinically applicable tissues/organs at relevant volumes.

METHODS: We prepared hollow microparticles (HPs) loaded with an emulsion of the oxygen carrier perfluorooctane (PFO; PFO-HPs) for the timely supply of oxygen to surrounding cells. To investigate whether PFO-HPs provide a suitable environment for the cell survival and maintenance of osteogenic differentiation potency of human periosteal-derived cells (hPDCs) under hypoxia, hPDCs seeded on PFO-HPs were incubated under hypoxia. To determine whether PFO-HPs can supply sufficient oxygen for the survival of hPDCs and new bone formation by differentiation of hPDCs into bone cells, we used miniature pigs with mandibular defects as animal models.

RESULTS & DISCUSSION: PCL HPs were 100-500 μm spherical structures with an empty inner space like a balloon, and the average size of the PFO emulsion was ~300 nm. The PFO-HPs prolonged the survival and preserved the osteogenic differentiation potency of hPDCs under hypoxia. hPDCs seeded onto PFO-HPs formed new bone at a faster rate and with a higher bone density than other groups.

CONCLUSIONS: Our findings suggest that PFO-HPs provide a suitable environment for the survival and maintenance of differentiation ability of hPDCs at bony defects without vascular networks until new blood vessel ingrowth occurs, thus enhancing bone regeneration. PFO-HPs are a promising system for effective delivery of various functional cells, including stem cells and progenitor cells, to regenerate damaged tissues/organs.

INTRODUCTION: In the field of tissue engineering, biodegradable scaffolds have been used as supporting tools for cell proliferation and/or appropriate matrix formation (i.e., protein synthesis) to fill tissue defects with cells. In this study, we manufactured a complex of human nasal septal cartilage (hNC) with polycaprolactone (PCL) for transplantation into cartilaginous skeletal defects and evaluated their characteristics.

METHODS: Nasal septum tissue was obtained from five patients aged ≥ 20 years who were undergoing septoplasty. hNCs were isolated and subcultured for three passages in vitro. To formulate the cell–PCL complex, we used type I collagen as an adhesive between chondrocyte and PCL. Immunofluorescence staining, cell viability and growth in the hNC–PCL complex, and mycoplasma contamination were assessed.

RESULTS & DISCUSSION: hNCs in PCL showed viability ≥ 70% and remained at these levels for 9 h of incubation at 4°C. Immunostaining of the hNC–PCL complex also showed high expression levels of chondrocyte-specific protein, Type II collagen, Sox9, and aggrecan during 24 h of clinically applicable conditions.

CONCLUSIONS: The hNC–PCL complex may be a valuable therapeutic agent for implantation into injured cartilage tissue, and can be used clinically to repair cartilaginous skeletal defects. From a clinical perspective, it is important to set the duration of the implantation process at ≤ 9 h to achieve effective functional implantation.

INTRODUCTION: Type 1 diabetes (T1D) is an autoimmune disease characterized by destruction of pancreatic β cells. Construction and immunoprotection of beta cell organoids are eligible strategies for islet therapy research in T1D [1,2]. In this study, we have investigated coating of β-TC-6 islet organoids with PEG-lipid microgels through hydrophobic interactions.

METHODS: β-TC-6 islet organoids were formed by hanging drop method. PEG microgels were synthesized through water-in-water (W/W) technique with different ultrasonic powers (30%, 60%) and emulsification durations (10, 30, 45 min) for size optimization. As a lipid functionality acrylate-PEG-DSPE was covalently attached to the microgel. Emulsion was then photopolymerized with 514 nm visible light. Islet organoids were coated by PEG-lipid microgels with different DSPE (2.5 mM, 5mM) and microgel (10 mg/ml, 20 mg/ml) concentrations, addressed here as 2.5DSPE10, 5DSPE10, 2.5DSPE20 and 5DSPE20.

RESULTS & DISCUSSION: Wet emulsion microscopy images of PEG-lipid microgels were analyzed by Image J and size distribution was found as 2-3 μm. The smallest microgel diameter was obtained as 2.13 μm with 60% power and 30 min ultrasonication. PEG-lipid microgels were fluorescently labeled with fluorescein-o-acrylate to confirm the deposition of microgels around organoids by hydrophobic interactions between cell membrane and DSPE group. Viability of the organoids increased when DSPE concentration was doubled from 2.5 mM to 5 mM. We observed highest apoptotic activity for in cells coated with 5DSPE20. Stimulation index for all groups were higher than 1 which indicates organoids are functional and can secrete insulin in response to high glucose before and after PEG-lipid microgel coating.

CONCLUSIONS: For all conditions studied, coated β-TC-6 islet organoids retained their insulin secretion function and viability. This approach is promising for immunoisolation of islet organoids to generate thin protective barriers without disturbing the cell membrane.

INTRODUCTION: Chitosan is a well-known bioadhesive polymer that is a suitable candidate for drug and gene delivery systems due to its tunable properties and cationic nature \cite{1}. Here, we aim to synthesize biofunctional chitosan nanoparticles together with water soluble polymer PEG and plasmid DNA (pDNA) encoding TNF-related apoptosis inducing ligand (TRAIL). TRAIL is well-known for inducing apoptosis in cancer cells rather than healthy cells \cite{2}. Hence this proposed system will have potential to be used as a gene delivery vehicle to promote apoptosis and decrease the viability of glioblastoma multiforme.

METHODS: Transfection studies were performed on HEK293-T and FMC-U87MG cell lines. HEK293-T and FMC-U87MG cells were co-cultured at a ratio of 1:4 and seeded in a 24-well plate as triplicates. After 24 h, transfection medium containing serum-free media and nanoparticle solution were added onto the cells and incubated for overnight. Cells’ fluorescence and bioluminescence were measured after 48 h of post-transfection.

RESULTS & DISCUSSION: We propose transfection of GBM cells using chitosan-PEG-TRAIL nanoparticle system, where apoptosis in GBM cells can be achieved through co-culture of GBM cells with HEK293-T. Based on this approach, transfected HEK293-T cells were used to achieve secretion of TRAIL protein. For co-culture experiments, we used engineered U87MG cells that express the fusion of mCherry and firefly luciferase along with HEK293-T cells. We observed increased amount of GBM cell death with the secretion of TRAIL. We also found that after 24 h of post-transfection, only 25\% of GBM cells remained in the medium.

CONCLUSIONS: We concluded that chitosan-PEG-TRAIL nanoparticle system significantly inhibited U87MG proliferation when these cells were co-cultured with HEK293-T.

INTRODUCTION: Stromal Vascular Fraction (SVF) is well known as adipose tissue–derived heterogeneous cells due to its high potential clinical applications. Based on our previous studies using Hyaluronic Acid-Gelatin loaded Biphasic Calcium Phosphate scaffold (HyA-Gel/BCP), we confirmed that ECM like HyA-Gel hydrogel loading was significantly improved the new bone formation by the fast attachment and migration of osteoblast cells. In this study, we focused on the effect of autologous SVFs loading on osteogenesis in HyA-Gel/BCP scaffolds by in-vitro and in-vivo approaches.

METHODS: SVF were isolated from the inguinal fat pad of rats. Isolated SVFs were seeded on the pre-conditioned HyA-Gel/BCP scaffolds and cultured for 3 days in incubator (37°C, CO₂ 5%). Isolated SVFs were analyzed by Flow cytometer (CD31, CD73, CD45). Cell attachment was estimated by Scanning Electron Microscopy. In-vitro biocompatibility was analyzed by MTT assay for 1 days, 5 days and 7 days. In-vivo studies were performed by craniotomy for 4 and 8 weeks using sprague-dawley rats.

RESULTS & DISCUSSION: Stromal vascular fractions were successively isolated from the inguinal-fat-pad of rats. From the in-vitro studies, the isolated and cultured SVFs expressed the typical MSC markers such as CD73⁺, CD45⁻ and CD31⁻. SVFs were cultured on the HyA-Gel/BCP scaffolds for 3 days, 5 days and 7 days. From the SEM observation, SVFs were attached and expanded actively on the scaffolds after 5 and 7 days. The results of MTT assay indicated that SVFs were well proliferated without toxicity on HyA-Gel/BCP scaffolds. In-vivo experiments were performed by using 3 groups: control, HyA-Gel/BCP and SVF loaded HyA-Gel/BCP groups. Most of bone grafted zones using HyA-Gel/BCP and SVF loaded HyA-Gel/BCP groups were covered with new bones without any inflammation and foreign body reactions. Detailed quantitative analysis by u-CT analysis indicated that the value of BV/TV ratio in SVF loaded HyA-Gel/BCP scaffolds showed higher than that of HyA-Gel/BCP group.

CONCLUSIONS: Due to the excellent biocompatibility, the isolated autologous SVFs were attached and proliferated actively on the HyA-Gel/BCP scaffolds. In-vivo experiment using craniotomy on rat skulls showed that SVFs loaded HyA-Gel/BCP scaffold improved remarkably the new bone formation. Thus we can say that autologous SVFs loading on scaffolds will have a potential for clinical application.

INTRODUCTION: Lesions to the peripheral nervous system are considered a key area for the development of regenerative treatments. Although a myriad of factors can cause neuropathies (traumatic injuries, iatrogenic effects, and diabetes are responsible for most of the cases), current treatments do not allow for total regeneration. Disability, sensory deficiencies, development of neuropathic ulcers, pain, as well as higher levels of stress and depression arises as major side effect. Herein, we show a methodological characterization of poly(2-hydroxyethyl methacrylate) (PHEMA) based hydrogels envisioned as luminal fillers with potential for peripheral nerve regeneration [1–3].

METHODS: Macroporous hydrogels based on PHEMA were synthetized via redox-initiated free radical polymerization. Rheological analysis and swelling behaviour studies in different liquids (deionised water, minimum essential media, phosphate buffer saline, and ethanol) have been performed. Scanning electron microscopy images were acquired in order to visualize any changes in porosity. Incorporation of glycerol methacrylate (GMA) as a comonomer was studied to corroborate any improvements on mechanical properties and swelling behaviour. Polyethylene glycol dimethacrylate was used as a crosslinker.

RESULTS & DISCUSSION: HEMA and GMA were copolymerized via redox free radical polymerization to form soft and mechanically compliant hydrogels. These hydrogels, with elastic moduli in the range 5-10 kPa, can withstand the mechanical forces imposed during suturing and have reduced swelling, compared with PHEMA macroporous hydrogels, to prevent disruption of other structures. In addition, macroporous PHEMA hydrogels with elastic moduli in the range 0.9-1.6 kPa were synthetized using the same method. Although they are able to incorporate large quantities of liquids - such as deionized water, minimum essential media and phosphate buffer saline, their shape does not change and therefore, the possible constriction forces that could be imposed to the cellular environment are greatly reduced. SEM images were acquired to corroborate the presence of pores.

CONCLUSIONS: These hydrogels show potential for further functionalization to support axonal regrowth and Schwann cell infiltration via incorporation of molecules present in the extracellular matrix of the nerve such as laminin, or short polypeptides such as RGD or IKVAV. In addition, the project envisions the creation of micro- and nanotopographical cues by changing the crosslinker molecule to a degradable moiety.

ACKNOWLEDGEMENTS: Financial support was received from EPRSC and MRC Centre For Doctoral Training in Regenerative Medicine (studentship grant number: EP:L014904/1).

INTRODUCTION: Bone grafts are often inserted into defect sites in the jaw to encourage bone formation prior to inserting periodontal implants. As bone is relatively slower growing than the surrounding gum tissue then a barrier membrane (BM) is often used to prevent soft tissue overgrowing the site on grafts where bone formation is required.
Our aim was to develop a bilayer synthetic biodegradable BM that would act as a physical barrier for preventing epithelial invasion for up to 4 weeks without limiting the diffusion of waste and nutrients, and which would guide bone formation by ingrowth into a highly porous and interconnected bone-like structure.

METHODS: Each layers of the bilayer scaffold were firstly characterized separately. For layer 1 (L1), a pre-polymer of PCL was synthesized and methacrylated to obtain a photocurable polymer (PCLM). L1 was produced by casting of PCLM PolyHIPE under UV. MLOs (Murine long-bone osteocytes) were cultured on L1 for 21 days to assess cell viability and cell infiltration. Collagen and mineral deposition to scaffolds were measured. Resazurin reduction assay was performed for assessment of cell viability on each side. PolyHIPE scaffolds were finally assessed using an ex vivo chick femur defect model to show fully interconnected structure of the scaffolds. To produce a barrier layer (L2), we first electrospun PCL dissolved in 4 separate solvent compositions to find the best solute to manufacture random. We compared fiber dimeters and bead formation using SEM images. Human dermal fibroblasts (HDFs) were cultured on L2 to assess the barrier properties over 28days.

RESULTS & DISCUSSION: The results of the fluorescent and histological images proved that HDFs were not able to penetrate into the L2, while L1 encouraged the penetration and ingrowth of both MLOs and chick cells.

CONCLUSIONS: The bifunctional BM was successfully produced via emulsion templating and electrospinning. This novel bioresorbable membrane has potential to be used in GTR applications by acting as a barrier for epithelial cells at least for up to 4 weeks while allowing bone cells to grow in the implant zone.

INTRODUCTION: Human pluripotent stem cells (hPSCs)-derived cardiomyocytes (CMs) resemble immature embryonic or fetal CMs rather than mature adult CMs [1]. Therefore, generation of mature and subtype CMs from hPSCs is important for in vitro modeling of adult-onset cardiac disease and drug discovery [2,3]. Here, we identified maturation factors that could induce maturation and subtype specification of hPSC-CMs.

METHODS: We optimized differentiation protocols of hPSCs to CMs by evaluating cell seeding densities, concentrations of a Wnt activator, CHIR99021 and a Wnt inhibitor, IWP2, incubation times, and different media under feeder-free culture conditions. hPSCs were treated with various cytokines, growth factors, anti-oxidants, hormones, small molecules and signal pathway inhibitors. Maturity and atrial-like, ventricular-like, and nodal-like characteristics of hPSC-CMs were analyzed by qRT-PCR, immunostaining, flow cytometry, Western blot, and microscope imaging software.

RESULTS & DISCUSSION: Factors that enhance maturation and subtype specification of hPSC-CMs were selected by mRNA expression levels of a mature CM marker (cTnI), a ventricular CM marker (MLC2v), atrial CM markers (MLC2a, ANP, IRX4), a nodal CM marker (TBX18), smooth muscle cell markers (SMA, SM22), and an endothelial cell marker (CD31) (Figure 1). CM maturation and subtype specification factors were further confirmed by immunostaining, flow cytometry and Western blot with a ventricular marker (MLC2v), a sarcomere marker (sarcomeric alpha-actinin), and a T-tubule marker (caveolin-3). Beating CMs forming tubular-like structures were observed in maturation factor-treated groups compared to control group.

CONCLUSIONS: We identified several key molecules that enhance maturation and subtype specification of hPSC-CMs. These factors that could generate mature and subtype CMs are useful for cell-based in vitro disease modeling, drug screening and toxicity testing.

INTRODUCTION: Cryopreservation of germ cells is one of the leading technologies for assisted reproductive technology (ART), however, they are focused on embryos and oocytes. Ovarian follicle cryopreservation is one of the emerging issues to overcome current limitations and this is prerequisite for establishment of next generation ART [1]. In this study, we established optimal cryopreservation condition for pre-antral murine follicles.

METHODS: Murine ovaries and ovarian follicles of pre-puberty stage were isolated using mechanical dissociation. Cryopreservation was performed as status of whole ovary, half ovary and isolated single follicle, respectively. The cryo-solution was consisted with addition of 10% of ethylene glycol (EG), DMSO and 1M sucrose. The thawing was performed after 1 week of cryopreservation and ovaries and half ovaries were dissociated into follicles. The follicle culture media was consisted according to our previous studies [2,3,4] and factors X and Y was added. After maturation of each follicle, hCG (human Chorionic gonadotropin) and epidermal growth factor (EGF) were treated for ovulation.

RESULTS & DISCUSSION: Cryopreservation of whole ovaries and half-ovaries were significantly shrunken the ovaries and hard to isolate follicles and the cells seemed to be damaged as shown very dark color. Thawed follicles from cryopreserved as follicles demonstrated the survival and expansion in vitro. The addition of factors, X and Y, was significantly enhanced the survival. The thawed follicles successfully ovulated matured oocytes. And the matured oocytes was fertilized successfully in vitro.

CONCLUSIONS: Collectively, these data clearly illustrate the beneficial effect of factor X and Y for thawing of ovarian follicle after cryopreservation and the optimal status of murine ovary for long-term preservation.

INTRODUCTION: Bone morphogenic proteins (BMPs) are a group of cytokines belonging to the transforming growth factor-β (TGF-β) superfamily. As the BMPs play a major role in Skeletal development and bone formation, disruption of their signaling induce different types of malformations [1]. Furthermore, BMPs have been unveiled as one the most potent growth factors in bone tissue engineering. Recently, 14 types of BMPs have been identified which regulate multilineage specific of stem cells including adipogenesis, osteogenesis, chondrogenesis and neurogenesis [2, 3]. The objective of this study was to compare osteogenic feature of different types of BMPs and evaluate their specific pathways.

METHODS: We investigated databases including “Pubmed”, “Scopus”, “Google Scholar” and “Web of Sciences” for related articles. Key words which were used for search were include “Bone morphogenic protein”, “BMP”, “Osteogenic differentiation”, “Bone tissue engineering”, “Bone regeneration”, “Osteogenesis”, “Signaling transduction” and “Signaling pathway”. Totally, 260 paper were found and finally 130 of them were chosen based and their relevancy, date of publication and number of citations.

RESULTS & DISCUSSION: We found that among 14 types of BMPs, BMP-2, BMP-6, BMP-7 and BMP-9 are the most potent osteogenic factors. In addition, utilization of BMP-9 has induced higher rate of mineralization and calcium content of stem cells compare to other types of BMPs. Resistance of BMP-9 to BMP-3 and noggin, as two well-known BMP antagonists, revealed that the differentiation pathway of BMP-9 is different from other osteogenic BMPs.

CONCLUSIONS: This study showed that BMP-9 is the most potent ostogenic BMP. Furthermore, it regulates bone formation in different intracellular pathway compare to other osteogenic BMPs.

ACKNOWLEDGMENTS: The authors would like to thank the personnel of Erfan hospital for assistance in this research. We also thank Ms Tayebi for her assistance during professional laboratory works. INTRODUCTION: Utilization of cell therapy in order to heal the refractory wounds has been emerged during recent decades. Among copious types of cell delivery methods, cell spraying has showed promising way compare to other [1]. However, new methods and technologies are growing fast which specify the need for further evaluations. Therefore, the objective of this study was to evaluate various methods and technologies in cell delivery with focus on cell spraying.

METHODS: A review of literature was conducted using Web of Science, Pub Med, and Google scholar from 2005 to the end of 2018. The keywords were “cell spray”, “stem cells”, “cell aerosols”, “cell delivery”, “keratinocyte cell spray”, “fibroblast cell spray”, and “wound healing”.

RESULTS & DISCUSSION: An overview of cell therapy by cell spraying method for chronic ulcers and different grades of burns is presented in this review. In addition, the differences between the details of cell spraying methods including various cell sources and spray-on cellular compounds are also summarized. Finally, the results of animal experiments and clinical trials are expressed and compared with each other.

CONCLUSIONS: Techniques used for management of wounds have differed from autologous full-thickness grafts and mesh expansion of split-thickness skin grafts [2] to new conservative methods. However, reducing removed skin to cover the exposed areas [1] and wound re-epithelialization time [2] were required to optimize transplantation outcomes. Spray-applied cell therapy has recently drawn great attention as a less invasive method approaching these ideals. According to studies, although cell spray does not alter the basic surgical indications and principles of epidermal replacement [1], promotion of carrier and application technique would bring it to the near future cell transplantation techniques.

ACKNOWLEDGEMENTS: The authors thank Dr. Tayebi for their assistance in this research. Research reported in this publication was supported by Researcher Grant Committee under award number [963951] from the National Institutes for Medical Research Development (NIMAD), Tehran, Iran.

INTRODUCTION: Tissue engineering is a novel scientific approach for repair or replace damaged organs and lost tissues. Scaffolds with suitable electrical properties are critical for the success of nerve tissue engineering. The objective of this study was to fabricate a conducting scaffold based on polypyrrole. In order to enhance cell interactions, polypyrrole was blended with alginate and nanochitosan. [1-2]

METHODS: 0.1 M pyrrole in 1 N HCl solution was added to 3% Alg solution and stirred. Then, FeCl3 was added drop wise and solution was stirred for 5 h. This polymer blend was isolated from the reaction mixture by dialyzed to remove oxidant and unreacted substances. 3 wt% nanochitosan solution was prepared by dissolving nanochitosan in acetic acid solution and finely powdered 1 wt% PPy–Alg was added. The samples were further lyophilized in a freeze dryer system. The freeze-dried samples were then cross-linked with glutaraldehyde.

RESULTS & DISCUSSION: The electrical conductivity of Nanochitosan/polypyrrole–alginate composite has been measured by four-probe set up. The electrical conductivity of Nanochitosan/polypyrrole–alginate composite was found 1.3x10^{-4} ±0.00003 (0.556 mA), 3.1x10^{-4} ±0.00002 (1.133 mA) and 6.2x10^{-4} ±0.00002 (2.266 mA) which was comparable to natural conducting scaffolds.

CONCLUSIONS: According to the results of this study, it can be concluded that the developed nanochitosan/PPy–Alg composite scaffold has electrical conductivity which is suitable to serve as a substrate of stem cell for nerve tissue regeneration.

INTRODUCTION: The idea of tissue decellularization is a promising approach to obtain the biologic scaffolds while preserving the extracellular matrix (ECM) integrity and bioactivity [1-2]. However, the currently applied decellularizing methods alter tissue structure as well as physical and biochemical properties of the remaining ECM, which in turn affect the host response to the material. Minimization of these undesirable effects is the objective of decellularization approaches [3]. The focus of this study was to present the recent advances on decellularization protocols of tissues and whole-organs.

METHODS: A literature search was conducted on PubMed, Scopus, and Google Scholar. Keywords were: ‘Optimized Decellularization’, ‘Whole-Organ Decellularization’, ‘Tissue Decellularization’, ‘Acellularization’, and ‘Biological Scaffold’. The search was limited to journal articles published in English from 2010 to the end of 2018.

RESULTS & DISCUSSION: Two main factors which contribute to protocols efficacy are decellularization agents and techniques of applying the agents. Commonly used agents include chemical, biological molecules, and physical approaches. Frequently employed techniques were whole-organ perfusion, pressure gradient induction, agitation, and treatment with supercritical fluids. The most effective agents and techniques depend mainly on tissue characteristics including cellularity, density, lipid content, and thickness.

CONCLUSIONS: The optimal decellularization of tissues requires a combination of different agents and techniques, including chemical, biological, and physical approaches. However, further works will be required to optimize the combinations of approaches for complete removal of cell components.

INTRODUCTION: Blood concentrates are obtained by centrifugation of the patient’s own peripheral blood. These concentrates revealed increasing importance in the regenerative medicine and tissue engineering. Many limitations are faced in preclinical research concerning the volume of blood needed to produce platelet-rich fibrin (PRF) matrices (10 mL). This study evaluated for the first time three different centrifugation protocols to obtain injectable PRF (i-PRF) matrices using a small blood volume of 3 mL.

METHODS: Small tubes were specially produced for this study. Blood was collected from 24 Wistar rats (ca. 200 g) for this study using the cardiac puncture technique. From each animal, two tubes were collected: the first was prepared according to the standard PRF protocol without anticoagulation and used for in vitro culturing and histology; the second was anticoagulated and used for automated cell count. Three different relative centrifugation forces (RCFs; high [710 g], medium [177 g], and low [44 g]) were evaluated in this study (n = 8 per RCF). The obtained PRF matrices were cultured over 10 days, and the supernatants were collected for quantification of growth factors (GFs), vascular endothelial growth factor (VEGF), transforming growth factor beta 1 (TGF-b1), and platelet-derived growth factor-BB (PDGF-BB).

RESULTS & DISCUSSION: The results showed that it is possible to produce i-PRF using a small blood volume of 3 mL. Reducing the RCF led to a significant increase in the number of platelets and leukocytes, specifically lymphocytes, within the i-PRF matrices. GF release (VEGF, TGF-b1, and PDGF-BB) was continuously measurable in all evaluated i-PRF matrices over 10 days. The i-PRF matrices prepared using low RCF released significantly more GF compared to those prepared using a medium or high RCF over 10 days (p < 0.05). These findings are in accordance with the previously described low-speed centrifugation concept (LSCC), which was first established using human blood, and may serve as a proof of concept of the LSCC in another species, that is, rats.

CONCLUSIONS: Reducing the initial blood volume provides many possibilities to implement PRF matrices in preclinical research as an autologous system. However, further studies are needed to evaluate the therapeutic effects of PRF matrices obtained using 10 mL blood compared to those obtained using 3 mL blood.

The recent advances on the role of placenta stem cell and comparison with other sources in cell therapy of wound healing
M. Kazemzadeh Hemmesi¹,²†, S. Shariatzadeh¹,²†, H. Niknejad¹

INTRODUCTION: Appropriate treatment and management of a wound and its consequent scar increases the patient’s quality of life and also reduces the costs in health care system. Since injured skin is regenerated by self-renewal and differentiation of skin progenitor stem cells, applying stem cells into wounds is a current therapeutic alternative. In this study, we focused on the advances about role of stem cell types on wound healing process.

METHODS: Articles retrieved from EMBASE, PubMed and Google scholar; published in English between years 2008 and 2018; Using following keywords: "stem cell", “Placenta”, “cell therapy”, “non-healing wound”, "wound healing" and/or "burn". Through the large number of studies, 115 original articles reviewed.

RESULTS & DISCUSSION: Stem cells can be derived from a variety of origins including bone marrow, adipose tissue, cord blood and extra-fetal tissue, embryonic and induced pluripotent stem cells (iPSCs), menstrual blood, and skin. Stem cells empower wound healing process by the following mechanisms: 1) Inducing angiogenesis by both releasing growth factors and direct differentiation to vasculature cells, 2) Differentiation into fibroblasts and keratinocytes [1] and 3) Inducing inflammation by cytokine release [2]. Bone marrow mesenchymal stem cells (BM-MSCs) and adipose-derived mesenchymal stem cells (AD-MSCs) have been more frequently studied in wound healing. Extraction of BM-MSCs from iliac crest is difficult whereas AD-MSCs can be simply achieved from peripheral fat tissue. Despite the pluripotent nature of embryonic stem cells and their differentiation into keratinocytes are favorable, their usage is still controversial due to the probable potential of immune rejection, teratoma formation and also ethical concerns. Yet using iPSCs reported to provoke less immunoreactivity in comparison to the other stem cell types. Stem cells from the placenta also considerably affect skin regeneration, while can circumvent the challenging problems of the other sources.

CONCLUSIONS: Wound healing process does have its particular needs based on the properties of each wound. While any of stem cell types imposes common or distinct healing mechanisms, usage of each stem cell type on a particular wound, will result in a broad range of clinical efficacy. Although there have been much advances in understanding of placenta stem cells therapeutic features in wound healing, it seems there are still a lot to find out by future investigations.

INTRODUCTION: Human Amniotic membrane (HAM) has various potentials for therapeutic purposes including angiogenesis and anti-angiogenesis which is surface dependent. Recently exosomes have gained a lot of attention to be as a carrier for a variety of macromolecules which control intracellular communication. The aim of this study was to evaluate the influence of Amnion-derived exosomes on angiogenesis [1-3].

METHODS: HAM was isolated from the placenta and cultured into a serum-free 12 well plate. The condition media was collected after 24 hours and their exosomes were isolated using Exocib kit. The exosomes were characterized by transmission electron microscopy and dynamic light scattering. The angiogenesis activity of Human amnion-derived exosomes(hA-Exo) was assessed by In vivo rat dorsal skinfold chamber.

RESULTS & DISCUSSION: Transmission electron microscopy of hA-exo showed a typical cup-shaped morphology (figure1). The number of vessel sprouts and their length were affected significantly by the compositions of hA-exo.

CONCLUSIONS: This study showed that hA-exo affect angiogenesis which can be as a candidate for cardiovascular disease therapy.

¹Tissue Engineering Research group, University of Bergen, Norway

INTRODUCTION: Three-dimensional (3-D) culture of mesenchymal stromal cells (MSCs) represents a novel strategy to enhance their regenerative properties for tissue engineering applications, by more closely simulating the in vivo microenvironment vs. 2-D monolayer culture [1]. MSCs exert their regenerative effects mainly via paracrine mechanisms [2]. The objective of this study was to investigate differences in the gene expression and cytokine profile (secretome) of 3-D and 2-D cultured MSCs in vitro.

METHODS: Human bone marrow MSCs (BMSCs) and gingiva-derived progenitor cells (GPCs) were isolated and characterized for immunophenotype and multipotency, in xeno-free medium supplemented with pooled human platelet lysate (PL). Passage 2 cells were subsequently cultured either in 2-D monolayers or as 3-D spheroids for different time periods to assess cell viability (live/dead stain) and gene expression. Conditioned medium (CM) from 3-D and 2-D cultured cells was collected after 48h PL-free culture; contents were measured via a Multiplex assay and normalized to the amount of DNA to account for differences in cell numbers in 3-D and 2-D conditions.

RESULTS & DISCUSSION: BMSCs and GPCs cultured in PL demonstrated characteristic stromal phenotype and tri-lineage differentiation potential. 3-D spheroids were formed and maintained for up to 7 days with high viability (Figure 1). Expression of stemness- (Sox2, Oct4, Nanog) and osteogenesis-related genes (Runx2, BMP2) was significantly upregulated in 3-D vs. 2-D cultures (p<0.05). Multiplex analyses of CM revealed differential secretion of several cytokines, chemokines and growth factors, which were generally higher in 3-D vs. 2-D cultured cells; notably, secretion of FGF-2, SCGF- β, PDGF-BB, HGF and VEGF was significantly higher in 3-D vs. 2-D cultures of both GPCs and BMSCs (p<0.05).

CONCLUSIONS: 3-D culture enhances the in vitro secretory profile and stemness-related gene expression of MSCs compared to 2-D monolayers. Whether this is translated to enhanced regenerative effects of MSCs in vivo, should be investigated in future studies.

Figure 1: Morphology of 2-D (a) and 3-D (b, c) cultured GPCs. Cell viability after 7 days (d) suspension culture showing mostly live (green) and few dead (red) cells.

**INTRODUCTION:** The use of adipose derived stem cells (ASC) has been studied as a potential cell therapy with excellent outcomes [1]. These cells can be transplanted directly in the wound site or in combination with a biomaterial that acts as scaffold for them. Agarose have been reported as a biocompatible material that could be used in Regenerative Medicine [2]. Herein, we analyzed two different types of agarose in order to determine the best one to use as a scaffold for ASC transplantation.

**METHODS:** Scaffolds made with agarose gel (1.5%) of two different melting points (High and Low) were prepared in 24 well plates and were allowed to gel during 24 h at 37 °C. Then, murine ASC were seeded at 40,000 cells/well, and were allowed to attach for 24 h. After the seeding, the scaffolds were evaluated during four weeks, considering attachment and proliferation.

**RESULTS & DISCUSSION:** Even if the gel was stable during the four weeks, ASC seeded on high melting point agarose gel showed cell surface projections, the culture proliferated as lumps and no migration was observed. On the other hand, ASC seeded on the low melting point agarose gel adopted fibroblast-like morphology, they didn’t proliferate in lumps, also both migration and spreading were observed. In low melting point agarose gel, scaffolds showed lower stability, and it lost structure during the third week.

**CONCLUSIONS:** Murine ASC were able to attach in both agarose scaffolds but they adopted different morphology and growth dynamics, due to the mechanical differences of the agaroses indicating that the strength of the scaffold can affect the behavior of ASC. Thus, is crucial to study how interaction of ASC with biomaterials could change their regenerative properties. This work represents the first steps of research using ASC in combination with biomaterials to improve wound healing for Costa Rican population.

INTRODUCTION: Chronic skin wounds (CSWs) are a global health problem, affecting patients’ quality of life and healthcare system finance. In this context, there is an urgent need of innovative treatments to trigger healing and tissue regeneration. In this contribution, new thermosensitive injectable sol-gel systems were designed as potential carriers of biomolecules (i.e. platelet lysate) in CSWs treatment.

METHODS: Two different PUs were synthesized [1] starting from two commercially available poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) triblock copolymers (Poloxamer P407 and F68), to modulate thermosensitivity in the resulting gels. An aliphatic diisocyanate and an amino acid derived diamine (L-lysine ethyl ester) were used as diisocyanate and chain extender, respectively. The obtained PUs (PU_P407 and PU_F68) were chemically characterized by Size Exclusion Chromatography (SEC) and Fourier Trasformed Infrared (FTIR) spectroscopy. PU aqueous solutions were characterized by tube inverting, gelation time test at 37°C, injectability and rheology to assess their temperature-driven sol-to-gel transition. Swelling and stability to dissolution were also evaluated. Model proteins (bovine serum albumin, horseradish peroxidase, -HRP-) were encapsulated and their release was studied by bicinchoninic acid assay (BCA assay)

RESULTS & DISCUSSION: PUs were successfully synthesized as assessed by SEC and FTIR spectroscopy. Sol-gel systems with gelation temperature in the range 20-35°C, sol-to-gel transition at 37°C within 10min and injectability through commercial needles (G22, G18, G14) at 5, 25 and 37°C were designed. Rheological characterization showed a full development at 37°C for PU_P407 gels, while PU_F68 systems were still in the sol phase, despite their gel-like behavior due to their rubber consistence. Consequently, gel residence time in aqueous environment for PU_F68 systems was limited to 1-3 days, reaching 7-14 days for PU_P407 gels. Hence, encapsulation and release studies with model proteins were performed only on PU_P407 gels, demonstrating their capability to load and release biomolecules in a controlled and sustained way.

CONCLUSIONS: Injectable thermosensitive sol-gel systems were successfully designed as promising platforms in the treatment of CSWs.

ACKNOWLEDGEMENTS: This work was financially supported by PREVISION “Prognostic evaluation of the use of three-dimensional bioactive scaffolds and injectable gels for the treatment of chronic lesions of the skin by means of new biomedical imaging technologies” project, financed by Fondazione Pisa.

3D-printing of platelet rich plasma based ink for cartilage tissue regeneration
S. Carluccio¹, M.E. Palamà¹, C. Gentili¹
Presenting Author: Simonetta Carluccio, simonetta.carluccio@edu.unige.it
¹Department of Experimental Medicine DIMES, University of Genoa, Italy

INTRODUCTION: Therapies to regenerate human articular cartilage defects are still challenging due to poor tissue reparative potential and no self-renewing chondrocyte expansion in vitro. Among the innovative trends used for cartilage repair, in the last decade, Platelet Rich Plasma (PRP) has emerged as a promising therapeutic agent to promote tissue regeneration, since the growth factors contained in platelet granules trigger proliferative stimulus on human chondrocytes while maintain their somatic differentiation potential [1]. Recently, tissue engineering and regenerative medicine fields are pushing on 3D bioprinting as novel method for the 3D fabrication of living tissue-like structures based on the capability to create cell-laden scaffolds with predesigned architecture and distribution of biological factors [2]. Here we produce a new type of bioactive-ink for 3D printing with the aim of encapsulating human articular chondrocytes in enhanced scaffolds able to promote cellular functions and finally chondrogenesis by supplying a sustained quantity of growth factors.

METHODS: Scaffolds were realized by a 3D-extrusion bioprinter, starting from a nanofibrillated cellulose and alginate ink mixed with PRP (2 × 10⁶ platelets/ml) in combination with human primary articular chondrocytes. The realized constructs were then cross-linked in a CaCl₂ solution (50mM) subsequently to the printing, thus obtaining a freestanding structures. PRP growth factor release through the constructs was characterized prior to encapsulate cells. Chondrocyte-laden scaffolds were cultivated in chondrogenic medium (containing TGFβ) and assessed for cell viability and proliferation in vitro. The ability to sustain the in vivo chondrogenesis was checked by subcutaneous implantation of the printed constructs in nude mice for 1 month followed by histological analysis of those recovered.

RESULTS & DISCUSSION: Embedding of PRP in the printed constructs supports the chondrocyte viability and growth in the scaffold in comparison to control constructs realized without adding of biological factors. The gradual and controlled release of growth factors from platelets is achieved during culture time, thus obtaining a beneficial micro-environment for cell functions and their interactions. The in vivo test demonstrates cellular production of a glycosaminoglycan-positive matrix and organization in a hyaline-like cartilage tissue more consistent than control group without platelet derivatives.

CONCLUSIONS: 3D bioprinting allows to realize custom-made and autologous cartilage-like constructs available in the injury treatment or even surgery. The introduction of PRP improves the biological function of a standard printable ink and it offers the opportunity for the controlled and localized delivery of growth factors with the aim to stimulate cartilage regeneration and survival.

INTRODUCTION: Orthopedic implants made of Ti alloys often suffer from poor adhesion to the tissues that can be overcome by using additional biocompatible coatings from calcium phosphates. However, such coatings do not stick sufficiently to the metallic surfaces, hence very thin interfacial layers of transition metal carbides can be added to increase adhesion, corrosion resistance and cell proliferation of the implants.

METHODS: The coatings were deposited by RF magnetron sputtering on Ti-6Al-4V discs using HAP, TiO2 and NbC, ZrC or TiC high-purity targets. The adhesion was evaluated by an examination of the load at which the film flaking starts using the UMT-TriboLab platform (Bruker) The corrosion behavior was tested in SBF solution using a PARSTAT 4000 Potentiostat. Biological tests were carried out on human osteosarcoma cells line MG63 (American Type Culture Collection) and to estimate the proliferation level, the DNA amount was measured.

RESULTS & DISCUSSION: The presence of the interfacial carbide layer does not prevent the formation of the HAP phase. In addition, complex coatings exhibit increased resistance to cracking and spallation with respect to the reference, indicating beneficial effect of that layer to the adhesion between d-HAP and Ti6Al4V alloy. All coatings with carbide interfaces exhibited also higher breakdown potential values than the reference coating and uncoated substrate, which can prove that the addition of a metallic carbide interlayer improves anti-corrosion performance. Similar observation concerns higher proliferation level after both 3 and 7 days of culture, compared to the reference.

CONCLUSIONS: Presented data clearly illustrate that carbide-based adhesion layers might be promising solutions to improve bonding performance between various HAP coatings and Ti6Al4V orthopaedic implants.

Elevated WNT5A and WNT11 during MSC chondrogenesis: WNT inhibition lowers BMP and Hedgehog activity and reduces hypertrophy

S. Diederichs¹, V. Tonnier¹, W. Richter¹

Presenting Author: Solvig Diederichs, solvig.diederichs@med.uni-heidelberg.de

¹Research Center for Experimental Orthopaedics, Center for Orthopaedics, Trauma Surgery and Paraplegiology, Heidelberg University Hospital, Heidelberg, Germany

INTRODUCTION: During in vitro chondrogenesis, bone marrow-derived mesenchymal stromal cells (MSCs) proceed along the endochondral pathway and develop an inherent mineralization activity leading to bone formation at ectopic sites, which is undesired for cartilage regeneration. In contrast, articular chondrocytes (ACs) re-differentiate into a stable articular phenotype and form no bone under the same conditions. The signals driving MSCs into hypertrophy are still incompletely understood. WNT signaling controls endochondral ossification during limb development. We here aimed to illuminate the relevance of WNT signaling for endochondral MSC differentiation, specific candidate drivers in the complex WNT network and the potential crosstalk with other presumably pro-hypertrophic pathways, i.e., BMP and hedgehog (HH) signaling. Better knowledge will allow improved articular cartilage neogenesis in vitro and provide novel therapeutic strategies for regeneration of cartilage tissue in damaged joints.

METHODS: Expression of 71 WNT network genes was assessed via microarray at day 28 of human MSC chondrogenesis and AC re-differentiation and genes of interest verified via qPCR in independent time course experiments. β-catenin, WNT5A and WNT11 levels were detected by Western blotting. WNT signaling during MSC chondrogenesis was blocked with IWP-2 (2µM from day 14 on) and effects were compared with our most potent anti-hypertrophic treatment, pulsed PTHrP(1-34), by monitoring endochondral markers, BMPs, IHH and their targets via qPCR. Ectopic bone formation was assessed after subcutaneous implantation into immune deficient mice via micro CT and histology.

RESULTS & DISCUSSION: 11 WNT genes showed a more than 2-fold different mean expression between re-differentiated ACs and MSC-derived chondrocytes. 9 out of these were higher expressed in MSC-derived chondrocytes. Assessment of WNT ligands showed that high levels of non-canonical WNT5A early and WNT11 late discriminated MSC chondrogenesis from AC re-differentiation. Also, β-catenin seemed incompletely silenced in the MSC group. This suggested higher WNT activity in MSC-derived chondrocytes. WNT inhibition with IWP-2 supported chondrogenesis according to proteoglycan deposition and COL2A1 expression and reduced the pro-hypertrophic transcription factor MEF2C and multiple downstream targets including IBSP and ALPL mRNA, and ALP activity. In addition, IWP-2 treatment lowered BMP4, BMP7 and the BMP target gene ID1. In addition, IHH along with its target GLI were suppressed. This demonstrated that WNT activity drove MSC hypertrophy in crosstalk with BMP and HH signaling. WNT inhibition almost matched the strong anti-hypertrophic capacity of PTHrP(1-34) pulses, yet, hypertrophic marker expression remained above AC level and in vivo mineralization and ectopic bone formation were reduced but not eliminated.

CONCLUSIONS: WNT inhibition was anti-hypertrophic but not powerful enough to re-direct MSC chondrogenesis to articular cartilage neogenesis. Thus, in view of the here discovered crosstalk, a combinatorial inhibitor approach may be promising to fully silence the pro-hypertrophic network during MSC chondrogenesis.
The effect of substance P/Heparin conjugated PLCL polymer coating of bioinert ePTFE vascular grafts on the recruitment of both ECs and SMCs for accelerated regeneration
D.H. Kim1,2, S.H Kim1,2,3,*
Presenting Author: Soo Hyun Kim, soohkim@kist.re.kr
1KU-KIST Graduate School of Converging Science and Technology, Korea University, 145 Anam-ro, Seongbuk-gu, Seoul, 02841, Republic of Korea 2Center for Biomaterials, Korea Institute of Science and Technology, Seoul 02792, Republic of Korea 3Department of Biomedical Engineering, Korea University of Science and Technology (UST), Daejeon 305-350, Republic of Korea

INTRODUCTION: Currently ePTFE vascular grafts are mostly used for treatment of vascular diseases. However, the issues of poor long-term patency and restenosis can arise after bypass surgery. Through a polymer coating, we intend to remodel bioinert ePTFE vascular grafts by creating an environment in which SMCs and ECs could grow together with bioactive molecules capable of instructing the surrounding tissues to migrate into the graft, inducing angiogenesis, and promoting regeneration.

METHODS: ePTFE vascular grafts put into Heparin conjugated PLCL polymer solution and/or Substance P conjugated PLCL polymer solution. Subsequently, Hep-PLCL coated ePTFE, SP-PLCL coated ePTFE, Hep/SP-PLCL coated ePTFE were implanted subcutaneously in SD-rats for 2weeks and 4weeks.

RESULTS & DISCUSSION: SEM and toluidine blue and anti-SP staining demonstrated that the surface and pore of ePTFE were uniformly coated. H&E staining illustrated significant increase of recruited cells into the grafts in SP-PLCL coated group and Hep/SP-PLCL coated group. The double staining of vWF and α-SMA revealed a significant increase of recruited ECs and SMCs in Hep/SP-PLCL coated ePTFE. CD68 and CD206 double staining revealed that Hep/SP-PLCL coating induced differentiation into anti-inflammatory M2 macrophage and inhibited pro-inflammatory macrophage infiltration. The MSC specific markers CD90 and CD105 were significantly more expressed in SP-PLCL and Hep/SP-PLCL coated ePTFE than the other groups.

CONCLUSIONS: Hep/SP Coatings allow grafts to be remodeled by creating a microenvironment where cells can grow by infiltrating into the grafts while also greatly enhancing angiogenesis. In particular, Hep/SP-PLCL showed markedly improved vascular remodeling through the recruitment of mesenchymal stem cells (MSCs), vascular cells (ECs, SMCs) and M2 macrophages.

Autophagy is needed during the differentiation of adipose derived stem cells to functional smooth muscle cells for use in bladder engineering
Presenting Author: Souzan Salemi, souzan.salemi@usz.ch
Laboratory for Urologic Tissue Engineering and Stem Cell Therapy, Department of Urology, University Hospital Zurich, Switzerland

INTRODUCTION: Tissue engineering using smooth muscle cells may provide a treatment option for diseases with smooth muscle pathology such as bladder dysfunction, urinary incontinence, and erectile dysfunction. As autologous smooth muscle cells (SMC) cannot be harvested from organs with end-stage diseases there is a need for other cell sources. Adipose derived stem cells (ADSC) can be easily harvested and differentiated into smooth muscle tissue. We have shown that autophagy, a conserved lysosomal degradation pathway, is required for cell survival and differentiation of adult stem cells. ADSC undergoing differentiation to SMC efficiently remodel their cytoskeleton and shape in an energy-consuming process. We investigated functional role of autophagy during differentiation and remodeling of ADSCs to SMC in vitro.

METHODS: Human and rat ADSCs were characterized and induced towards SMC using induction medium for 1 to 6 weeks. The changes in gene and protein expression level for SMC markers: calponin, smoothelin, α-SMA, MyH11; and autophagy related markers: LC3, Atg5, Beclin1 and p62 were investigated by real time PCR, ICC and WB.

RESULTS & DISCUSSION: Upon induction, up-regulation of Atg5-Atg12 and free Atg5 was observed during 4-6 weeks. This was supported by an increase in conversion of cytosolic LC3I to membrane-bound LC3II protein. At the same time the contractile proteins calponin, MyH11 and smoothelin were up regulated during 1-3 weeks and decreased after 5-6 weeks of differentiation detected by WB and ICC. Pharmacological blocking of autophagy by 3-methyladenine during the differentiation abolished the differentiation capacity of stem cells.

CONCLUSIONS: Our study demonstrates that autophagy plays an important role in ADSC differentiation to SMC. Influencing autophagy by pharmacological agents might be used to further optimize the induction to SMCs.

INTRODUCTION: The promotion of axonal survival and outgrowth is crucial in order to ensure peripheral nerve regeneration and has therefore been subject of intensive research during the past 20 years. One of the factors that drive neurite elongation are neurotrophic factors (NTF) which are retrogradely transported from the injured axonal tip to the neuronal cell soma. In this in vitro study, these survival and growth stimulatory factors were to be investigated for their neurotrophic potential on chicken embryonic dorsal root ganglia (DRG).

METHODS: DRG explants from 10 days old chicken embryos were isolated and cultured in culture medium enriched with either nerve growth factor (NGF), glial cell line-derived neurotrophic factor (GDNF), brain derived neurotrophic factor (BDNF), ciliary neurotrophic factor (CNTF), neurotrophin-3 (NT-3) or neurotrophin-4 (NT-4) at a concentration of 10ng/ml. As control, DRG explants were grown in NTF-free culture medium. After 48h of incubation time, axonal outgrowth was visualized by tubulin beta-III immune staining and the growth response was quantitatively analyzed by measuring the length and area of neurite outgrowth1,2,3.

RESULTS & DISCUSSION: Striking differences can be observed in the axonal outgrowth of DRG explants for distinct experimental conditions in terms of axonal count, elongation, density and branching. Interestingly, NT-3 and BDNF exerted the most potent neurotrophic effect as evidenced by axonal length and growth-area when compared to all the other conditions.

CONCLUSIONS: This in vitro study revealed the regenerative potential held by NT-3 and BDNF that even exceeded the stimulatory effect of potent and widely acknowledged growth factors such as NGF and GDNF. Further experiments in order to study the growth kinetics and the cell survival rate of NT-3 and BDNF treated neuronal cells are in progress.

**INTRODUCTION:** Adipose derived stem cells (AdSC) are known to enhance peripheral nerve regeneration when delivered in nerve conduits through distinct mechanisms. This study aimed at evaluating the synergistic effect of AdSC and nerve growth factor (NGF) in vitro and in vivo\textsuperscript{1,2,3} on axonal outgrowth.

**METHODS:** AdSCs were pre-treated with NGF (AdSC\textsuperscript{NGF}). Dorsal root ganglia (DRG) were cultured in conditioned medium (CM-AdSC\textsuperscript{NGF}) obtained from AdSC\textsuperscript{NGF}. Axonal outgrowth from DRG was visualized by immunostaining and evaluated by measuring the length and area of neurite outgrowth. For in vivo study, four rats per group were operated creating a 15mm gap on left sciatic nerve. AdSC\textsuperscript{NGF} were either integrated into the wall of FC or injected into the conduit’s lumen within a soft fibrin glue solution. Nerve ends were attached by a single suture to the conduit. Functional gait analyses were performed weekly. After four weeks, gastrocnemius muscles and sciatic nerves were explanted. The wet-weight of the muscles was measured and nerve tissue was process for immunostaining and microscopic analysis\textsuperscript{1}.

**RESULTS & DISCUSSION:** The secretome (CM-AdSC\textsuperscript{NGF} ) derived from AdSC\textsuperscript{NGF} exhibited significant axonal outgrowth from DRG explants when compared to controls. In vivo, all fibrin conduits, grafted for bridging the long-gap injuries, showed contraction. Muscle weigh loss was comparable across all groups. The distal nerve cross sections in experimental groups indicate incomplete nerve regeneration, whereas proximal cross sections show an axonal count close to autografts.

**CONCLUSIONS:** The study revealed the synergistic effect of AdSC’s derived secretome in the presence of NGF on axonal outgrowth in vitro. The suitability of fibrin conduits for treating long nerve gaps is to be evaluated. Although, the 15 mm long gap could not be crossed by regenerating axons within the 4 weeks, the axonal count in proximal part of the nerve and the reduced muscle weight loss indicate the potential of bioactive fibrin conduits for supporting axonal outgrowth over long-gaps.

INTRODUCTION: Porcine and fish by-products in particular are rich sources for collagen, which is the main component of the extracellular matrix (ECM). Although there are studies investigating different collagen derived from various tissue sources for the purpose of creating biomaterials, the comparison of biophysical, biochemical and biological properties of type II collagen isolated from cartilaginous tissues has yet to be assessed. In addition, it has been shown from previous studies that sex steroid hormones affect the collagen content in male and female animals, herein, type II collagens from male and female porcine cartilage were assessed in order to investigate gender effects on the property of collagen scaffolds. Therefore, the aim is to assess the properties of type II collagen scaffolds as a function of species, tissue and gender for cartilage regeneration.

METHODS: Type II collagen was extracted from male and female porcine trachea, auricular, articular cartilage and cartilaginous fish through acid-pepsin digestion at 4°C. Collagen sponges were created via freeze-drying. Sponges were seeded with human adipose derived stem cells to assess chondro-inductive potential of collagen sponges.

RESULTS & DISCUSSION: SDS-PAGE was performed to assess the purity of extracted collagen solution. In comparison with commercially available collagen types, SDS-PAGE confirmed the purity and molecular weight of collagen polypeptide chains of freshly isolated collagen from food waste. Previous studies demonstrated that higher denaturation temperature of collagen indicates higher thermal stability, which has been evaluated as a critical characteristic of collagen based medical devices. Cross-linker significantly increased thermal stability of collagen sponges in all groups, which means the crosslinking system that we used in this study helped to increase the denaturation temperature of collagen biomaterials. Collagen isolated from male and female articular cartilage exhibited higher resistance towards enzymatic degradation. All groups of collagen sponges support the proliferation and chondrogenic differentiation of human adipose derived stem cells.

CONCLUSIONS: In conclusion, collagen sponges support the proliferation and differentiation of human adipose derived stem cells to different extents.

INTRODUCTION: Adipose tissue has been reported to contain adult stem cells and several other cell types. Recently, adipose derived stromal vascular fraction (SVF) have been isolated from adipose tissue and applied in various research fields [1-3]. Among the different methods used to obtain stem cells, enzyme concentration and the duration of enzymatic treatment vary depending on the researcher; SVFs isolated conditions have not yet been optimally established. Therefore, we aimed to develop an automated system for the isolation of SVF.

METHODS: The yield and viability of SVF were evaluated by treating adipose tissue with 0.1% and 0.2% collagenase type I enzyme for 20, 40, and 60 min. Flow cytometry and colony forming units (CFUs) were analyzed for Adipose stem cells (ASCs) obtained by culturing the separated cells until passage 3. A cytokine array was performed to investigate the correlation between colony-forming ability and stemness.

RESULTS & DISCUSSION: Enzyme reaction with a collagenase concentration of 0.1% was increased number of SVF compared with 0.2% collagenase. However, an increase in enzyme reaction time to 60 min significantly reduced cell survival compared with the 40 min treatment. The CFU values were also higher when the processing time was 40 min compared with the 60 min in cells cultured up to passage 3. In addition, the higher CFU groups exhibited increased expression of growth factors, such as interleukin (IL)-6, IL-8, and monocyte chemoattractant protein-1, than lower CFU groups.

CONCLUSIONS: These results will provide researchers with an efficient method for the ASC isolation and can be useful reference for development of automatic system.

INTRODUCTION: Bone morphogenetic protein 2 (BMP-2) is one of the most effective osteogenic inductors in bone tissue engineering. Encapsulation of BMP-2 into biocompatible and bioresorbable materials protect it from rapid degradation under the influence of the environment and provide its uniform controlled release into surrounding tissue in a given local area. The purpose of our study was the development of porous bioactive scaffolds based on polylactoglycolic acid and BMP-2 using the methods of supercritical fluid (SCF) polymer plasticization followed by its foaming and surface-selective laser sintering. Comparative studies of BMP-2 release kinetics was performed in physiological saline.

METHODS: Polylactoglycolic acid porous (ca. 60 vol. %) scaffolds (PDLG 7507 PURAC Biochem BV) containing 10 µg/ml BMP-2 (Acron Biotech, USA, cat. AK8356) were manufactured by the supercritical carbon dioxide plasticization followed by foaming method at 33±0.1°C. Part of the scaffolds was subjected to additional processing by surface-selective laser sintering (SSLS) [1]. Fabricated scaffolds have a disk-like shape with a diameter of 5 mm and a thickness of 2 mm. The release kinetics of BMP-2 was determined using enzyme-linked immunosorbent assay (ELISA) using a standard ELISA kit for determining the concentration of BMP-2 (R&D, USA) in physiological saline.

RESULTS & DISCUSSION: Scaffolds fabricated by SCF only provided a smooth release of BMP-2 over 15 days. During this time, almost 100% of the encapsulated protein was released from the polymer. Laser sintering promotes longer retention of BMP-2 in the scaffolds. The peak release was observed from 13 to 15 days.

CONCLUSIONS: SSLS allows to maintain the biological activity of the protein within the volume of sintered particles [2]. Scaffolds obtained with SSLS have a dense surface layer that provides delayed release of protein. The combination of SCF and SSLS scaffold manufacturing methods allows the formation of structures with a controlled release rate of biologically active substances.

ACKNOWLEDGEMENTS: This work was supported by the Ministry of Science and Higher Education within the State assignment FSRC «Crystallography and Photonics» RAS in part of supercritical fluid BMP-2 encapsulations and within the State assignment FSBI «Research Centre for Medical Genetics» in part of BMP-2 release research and by Russian Foundation for Basic Research (Grant No. 18-32-20184) in part of laser assisted scaffolds design.

INTRODUCTION: The effective control of the stem cell metabolic status plays an important role in the determination of the certain stage of the differentiation, what is the actual problem of the cell biology and the regenerative medicine. In the process of the cell differentiation, the metabolic pathways are switched from the glycolysis to the oxidative phosphorylation. Presently, methods of the multiphoton microscopy with the fluorescent lifetime imaging actively introduced into biomedical researches. This method allows to evaluate the activity of cellular metabolic pathways based on the fluorescence lifetime and the contributions of free and bound forms of NAD(P)H during cell differentiation.

METHODS: In this study we evaluated the cellular metabolism of induced pluripotent stem (iPS) cells during dermal differentiation based on fluorescence lifetime of NAD(P)H using FLIM. IPS-KYOU line was purchased from ATCC cell Bank (USA). IPS-KYOU line were characterized using immunocytochemical analysis and quantitative real time RT-PCR in according to the expression of specific markers. This cell line was used as a base cell culture for obtaining directly differentiated dermal MSCs and keratinocyte precursors. iPS cells fluorescence imaging was performed using a confocal laser scanning microscopy LSM 880 (CarlZeiss, Germany) with FLIM mode. The excitation wavelength was set to 750 nm for cellular autofluorescence signals, with an emission signal range of 455 to 500 nm. The data were analyzed with the commercially available SPCImage software. The fluorescence lifetimes and their contributions (free and protein-bound forms of NAD(P)H: a free NADH, a bound NAD(P)H) for the areas of interest were calculated by finding the global minimum of the $\chi^2$ value for bi-exponential fittings.

RESULTS & DISCUSSION: During keratinocyte differentiation was shown a statistically significant increase in the contribution of bound NAD(P)H, indicating the rise of the oxidative phosphorylation contribution to the total cellular metabolism - a bound (iPS) = 15.09±2.65 %; a bound (keratinocyte precursors) = 21.02±1.34 %. However, in dermal MSCs derived from iPS no significant changes were observed in the contribution of the bound NAD(P)H - a bound (dermal MSCs) = 15.71±1.39 %, indicating the same glycolytic metabolism as in iPS.

CONCLUSIONS: The results extend the general understanding of functional changes in the process of iPS differentiation and open up new ways for the development of treatment strategies in regenerative medicine and stem cell therapy.

INTRODUCTION: It is a well-known fact that the liver has a high regenerative potential, and now an increasingly topical task is to study the mechanism of regeneration of liver tissue and search for methods of stimulation of this process. Traditional methods are not sufficient for accurate description of internal structure of heterogeneous cell populations and the dynamics of biological regenerative processes of the liver. Presently, methods of multiphoton microscopy with fluorescent lifetime imaging actively introduced into biomedical researches.

METHODS: It is highly informative, non-destructive and minimally invasive techniques, that allows to study a large number of processes occurring at the level of tissues and cells Also, these methods afford to analyze the molecular and cellular composition, as well as to assess the state of connective tissue fibers due to their ability to generate a second optical harmonic. In our work, we investigated metabolic changes and characteristics of collagen fibers in rat model of 30% and 70% hepatectomy at different stages of regeneration based on the fluorescence intensity level and the fluorescence lifetimes of metabolic cofactors (NAD(P)H, FAD) and second harmonic signal by the method of multiphoton microscopy with FLIM and SHG modes.

RESULTS & DISCUSSION: In this study, metabolic changes and formation of collagen fibers in rat model of liver resection were investigated based on fluorescence intensity level of metabolic cofactors (NAD(P)H, FAD) and second harmonic signal by multiphoton microscopy with FLIM and SHG modes. A separate analysis of NADH and NADPH were presented to assess the contribution of energy metabolism, as well as to evaluate the activity of lipogenesis in hepatocytes.

CONCLUSIONS: The obtained data can be used to develop new criteria for evaluation of metabolic and structural changes of hepatocytes aimed at personalized medicine in the future.

The characterization of collagen, silk fibroin and chitosan based materials for biomedical applications
S. Grabska¹, A. Sionkowska¹.
Presenting Author: Sylwia Grabska, sylwiagrabska91@gmail.com
¹Department of Biopolymer and Cosmetic Chemistry, Faculty of Chemistry, Nicolaus Copernicus University in Toruń, Poland

INTRODUCTION: Natural compounds can be used to obtain biomaterials as scaffolds, hydrogels or films. Due to low physico-chemical properties of single biopolymers there is a need to modify these materials by another biopolymers addition [1]. The materials can be also modified by cross-linking agent addition. The blending of collagen with other polymers can lead to preparation of new materials suitable for biomedical applications [2]. Materials based on collagen (Coll), silk fibroin (SF) and chitosan (CTS) were tested as the potential forms for tissue engineering purposes.

METHODS: The aim of the study was to characterize scaffolds obtained by freeze-drying method from collagen, silk fibroin and chitosan mixture after the cross-linking by EDC/NHS addition. Materials were characterized by the FTIR-ATR spectroscopy, porosity and density measurements, swelling behavior and mechanical parameters measurements. Collagen was prepared in our laboratory from tail tendons of young rats. Silk fibroin was prepared from Bombyx mori cocoons in our laboratory following the method described by Kim et. Al. with slight modifications [3]. Chitosan was supplied by the company Sigma-Aldrich (Poznań, Poland). The biopolymers were mixed together in appropriate weight ratio. The biocompatible scaffolds were obtained by freeze-drying method.

RESULTS & DISCUSSION: FTIR-ATR spectroscopy showed that between components of the blend there are interactions. Swelling tests were prepared. It was found that 3D composites made from collagen, silk fibroin and chitosan are hydrophilic with a high swelling ability. Cross-linking of such biopolymeric materials alters the swelling degree and porosity of materials. The cross-linking process has significant effect on the density of the materials. 3D materials based on Coll/SF/CTS are rigid and inflexible.

CONCLUSIONS: Strong interactions between two and three components in polymer blend can lead to new materials. The modification of physico-chemical properties can be a consequences of the strong interaction between the polymeric compounds. The properties of prepared materials depend on the mixture composition and content of the cross-linking agent.

ACKNOWLEDGEMENTS: Authors would like to thank for financial support from the PROM project from Polish National Agency for Academic Exchange.

INTRODUCTION: Parkinson’s disease (PD) is a long-term neurodegenerative disorder that affects about 1% of people over the age of 60. Degeneration of dopaminergic neurons, associated with mitochondrial dysfunction, oxidative stress, and apoptotic cell death, has a leading role in PD pathophysiology. Etiology of PD is still not completely understood. For example, the use of pesticides, particularly rotenone (a cytotoxic agent that inhibits complex I of the electron transport chain of mitochondria) is a cause of sporadic PD in people living in countryside. Low-intensity LED irradiation (LILI) is widely used for therapeutic purposes to stimulate cell metabolism, proliferative activity, and viability. The main target of LILI in cells is mitochondria. Therefore, the mechanisms of LILI can be studied on in vitro models using cellular respiration inhibitors, such as rotenone. This work aimed to study the effects of LILI on rotenone-induced PD model in vitro.

METHODS: The monolayer culture of human neuroblastoma cell line Sk-N-BE(2) was used in the work. Growth culture medium consisted of DMEM/F12 and 10% FBS. Continuous LILI was performed with two modes of LED light 1) 633nm, 1200s, 22kJ/m² and 2) 840nm, 600s, 21kJ/m² 2 hours before the culture was treated with the rotenone. Mitochondrial activity was suppressed by overnight culture exposure to rotenone (0,01-150µM). MTT and Alamar Blue assays were used to study cell viability. Apoptosis was detected by the Muse Annexin V and Dead Cell Assay Kit (Sigma, USA). Cells stained with Hoechst 33258 (Sigma, USA) and MitoTracker Green FM (ThermoFisher, USA) were monitored via live light time-lapse microscopy in CellInsight CX7 device (ThermoFisher, USA). Oxygen consumption rate (OCR) was measured by Seahorse assay.

RESULTS & DISCUSSION: Both LILI modes had a stimulating effect on the neuroblastoma cell line. The preliminary irradiation with 633 nm LEDs before rotenone treatment increased cell viability by 15% compared to non-irradiated culture. Irradiation at a wavelength of 840 nm affected a higher concentrations of toxin (half-lethal dose - 50 µM), increasing the cell viability by 20% on average. OCR in neuroblastoma cell line increased by 15% and 20% after irradiation with 633nm and 840nm LEDs, respectively. The irradiation of cells resulted in elevation of mitochondrial activity by 15%.

CONCLUSIONS: On the in vitro rotenone-induced PD model it was shown that LILI of impaired cells improved their viability and metabolic activity without cytotoxic effects on intact cells. LILI can find application as a therapeutic agent for PD.

ACKNOWLEDGMENTS: The study was supported by the Russian Science Foundation (15-15-00132, cell viability assays) and the Russian Foundation for Basic Research (17-02-01248, LED irradiation).
Bone marrow- versus adipose tissue-derived mesenchymal stem cells for the treatment of corneal failure in a rabbit model of limbal stem cell deficiency

INTRODUCTION: Limbal stem cell deficiency (LSCD) occurs as a result of limbal epithelial stem cell destruction or dysfunction, leading to vision loss and chronic inflammation of the ocular surface. Our research group has recently demonstrated that transplantation of bone marrow-derived mesenchymal stem cells (BM-MSC) onto the ocular surface of patients suffering from LSCD can safely and effectively help repair the corneal epithelium [1]. However, adipose tissue-derived MSC (AT-MSC) are more accessible, more cost-effective and a safer source of MSC than bone marrow. The aim of this work was to compare the efficacy of BM-MSC versus AT-MSC for the treatment of corneal failure due to LSCD in rabbits.

METHODS: Eighteen New Zealand white rabbits were transplanted with 250,000 MSC on amniotic membrane (9 with BM-MSC; 9 with AT-MSC) 3 weeks after inducing them a LSCD [2]. Nine non-transplanted animals formed the control group. Conjunctival invasion, corneal neovascularization, opacification, and epithelial defects were weekly examined on a slit lamp. Histopathology analyses at the end of follow-up (11 weeks) evaluated the level of tissue damage and the presence of lymphocytes (as a sign of inflammation) and goblet cells (as a sign of conjunctivalization) in limbal and corneal areas.

RESULTS & DISCUSSION: The BM-MSC-transplanted group showed less neovascularization and less corneal opacity at weeks 6-8, and 6-9, respectively than the untreated group. The AT-MSC-treated group had less conjunctival invasion and corneal opacity at weeks 6-8 and 6-10, respectively than the control group. There were no differences in the epithelial defects among the 3 groups. BM-MSC- and AT-MSC-transplanted groups showed higher number of corneal and limbal epithelial layers, less disorganization of the stroma, fewer inflammatory cells in the corneal stroma, and fewer goblet cells in the limbal or corneal epithelium than the untreated group.

CONCLUSIONS: Transplantation of BM-MSC and AT-MSC in a LSCD rabbit model reduced the development of corneal opacity, and partially restored the damaged limbal and corneal tissue structure. BM-MSC were superior in reducing the development of corneal neovascularization whereas AT-MSC better prevented conjunctival invasion. Both types of MSC seem valid alternatives for the treatment of LSCD.

Therapeutic ion loaded mesoporous nanoparticles for treating infections and biofilms in chronic skin wounds
Presenting Author: Thomas Paterson, t.paterson@sheffield.ac.uk

INTRODUCTION: Biofilms present within chronic skin wounds are difficult to treat and prevent wound healing. Silver and copper ions have been shown to be reliable antimicrobials. However, these antimicrobial agents are ineffective unless delivered to the site of infection. Mesoporous nanoparticles are one such delivery system that could act as a platform for delivering therapeutic ions. This project evaluates silver- and copper-containing mesoporous nanoparticles for their antimicrobial effectiveness, including testing them in a 3D tissue engineered skin infection model.

METHODS: Mesoporous glasses nanoparticles were manufactured using sol-gel methodology and then loaded with Ag+ and Cu2+. ICP was used to confirm ion loading. Monolayer fibroblast toxicity studies were conducted. Samples were tested using standard antimicrobial assays and tissue engineered infected skin models. The clinically relevant bacteria Staphylococcus aureus and Pseudomonas aeruginosa were used in the testing. SEM, viable colony count, PrestoBlue™, and crystal violet stain were used to assess biofilm viability. Biofilm formation and biofilm disruption were both examined.

RESULTS & DISCUSSION: Mesoporous nanoparticles successfully released ions and were non-toxic to mammalian cells at a concentration toxic to bacteria. Mammalian cells in tissue engineered skin were more resilient to silver releasing mesoporous nanoparticles than fibroblast monolayers. Silver nanoparticles were effective at preventing biofilm formation yet unable to disrupt established biofilms. Copper was equally effective against established and forming biofilms but was less effective than silver at preventing biofilm formation. In contrast to standard 2D assays, tissue engineered infection models showed the difficulty in treating established P. aeruginosa infections.

CONCLUSIONS: The mesoporous nanoparticles were non-toxic to mammalian cells at a concentration that exhibited antimicrobial properties. Tissue engineered skin was more resistant to treatment than simple 2D toxicity or antimicrobial tests. Depending on the bacteria microbiome, treating chronic infected wounds with these therapeutic containing mesoporous nanoparticles could reduce healing time by treating bacterial infections.

INTRODUCTION: Nowadays, microcarriers are widely utilized in drug delivery, defect filling, and cell culture [1-2]. Also, many researchers focus on the combination of synthetic and natural polymers and bioactive ceramics to prepare composite biomaterials for tissue engineering and regeneration [3].

METHODS: Poly (l-lactic) acid (PLLA) was fully dissolved in dichloromethane at a ratio of 1:10 (W/V) prior to being added into gelatin aqueous solution. A certain amount of nanohydroxyapatite (nHA) was added to the polymer solution, followed by mechanical agitation for two hours with a lid on to reduce the volatilization of dichloromethane. Then the gelatin-poly (l-lactic) acid suspension was stirred for 5h. The liquid beads gradually solidified and precipitated at the bottom of the beaker with the volatilization of organic solvent. Finally, the wet microcarriers were collected and dried in a vacuum drying oven.

RESULTS & DISCUSSION: In this study, PLLA, PLLA/nHA and PLLA/nHA/Chitosan (PLLA/nHA/Ch) were prepared based on physical doping and surface modification. Their physicochemical properties and functional performances in MC3T3-E1 cell culture were compared. Statistical results showed that the average diameter of PLLA microcarriers was 291.9 ± 30.7 μm, and that of PLLA/nHA and PLLA/nHA/Ch microcarriers decreased to 275.7 ± 30.6 μm and 269.4 ± 26.3 μm, respectively. The surface roughness and protein adsorption of microcarriers were enhanced with the doping of nHA and coating of chitosan. The cells-carrier cultivation stated that the PLLA/nHA microcarriers had the greatest proliferation-promoting effect, while the PLLA/nHA/Ch microcarriers performed the strongest attachment with MC3T3-E1 cells. Besides, the cells on the PLLA/nHA/Ch microcarriers exhibited optimal osteogenic expression.

CONCLUSIONS: Generally, chitosan was found to improve microcarriers with superior characteristics in cell adhesion and differentiation, and nanohydroxyapatite was beneficial for microcarriers regarding sphericity and cells proliferation.

Development of an alginate hydrogel for 3D printing
T. Robinson¹, J. M. Huyghe²
Presenting Author: Tiffany-Rae Robinson, 18035884@studentmail.ul.ie
¹The Bernal Institute, University of Limerick, Limerick, Ireland

INTRODUCTION: Alginate is a naturally derived polysaccharide material with a relatively low cost, excellent biocompatibility, and optimal chelating abilities. Furthermore, it has the potential to be used as a bioink in 3D printing, and is currently a choice material in tissue engineering and regenerative medicine applications [1-3].

METHODS: Alginic acid sodium salt from brown algae with medium viscosity (Sigma Aldrich) was crosslinked with Ca²⁺ to form an interpenetrating network (IPN) hydrogel. Multiple formulation methods of the hydrogel were examined including variations of the Ca²⁺ crosslinking agent and polymerization methods. The first hydrogel was formed via use of CaSO₄ and was polymerized by UV light. The second hydrogel was formed via use of CaCl₂ and was polymerized by an incubation period of 6 hours at 37°C. Both CaSO₄ and CaCl₂ were able to form a hydrogel, though differences in the clarity and mechanical properties were observed.

RESULTS & DISCUSSION: Qualitatively, the hydrogel formed via use of CaCl₂ was more uniform in structure and possessed better clarity than the hydrogel formed by CaSO₄. It is believed that this is due to the solubility of each compound in deionized water. Quantitatively, the swelling capabilities and compression strengths of both hydrogels were analyzed. The swelling capabilities were examined via weight analysis over a time range at: 5 minutes, 10 minutes, 20 minutes, 30 minutes, 1.5 hr, 1 day, 2 days, and 4 days. Additionally, after 4 days of swelling the gel underwent compression analysis. The CaSO₄ hydrogel had swelling capabilities of 144.6% and a compression strength of 12.4kN/m² when swollen. The CaCl₂ hydrogel is still currently undergoing testing.

CONCLUSIONS: Collectively, this data indicates that formulation of an IPN hydrogel synthesized from sodium alginate is possible via use of Ca²⁺ crosslinking. The mechanical properties, including viscosity, of the gel must be further examined and defined to transition this material towards becoming a bioink suitable for 3D printing by extrusion techniques.

INTRODUCTION: Different strategies such as autografts and nerve conduits are employed in the clinic to rejoin nerve endings after injury, but these bridging therapies are suboptimal and have several limitations. New therapeutic strategies to establish repair of injured nerves are therefore needed. For this purpose, our research group aims to combine Schwann cell differentiated human dental pulp stem cells with biomaterials such as Leukocyte- and Platelet-Rich Fibrin (L-PRF). L-PRF is a second-generation platelet concentrate that is characterized by a dense fibrin network rich in platelets, leukocytes and many soluble mediators. Platelet concentrates are innovative tools in regenerative medicine and their success in tissue repair and regeneration mainly depends on the release of growth factors. Recently, we showed that L-PRF has potent angiogenic properties and the goal of this project was to investigate the neurotrophic potential of this biomaterial.

METHODS: L-PRF was prepared by collecting blood samples of healthy human donors in glass-coated tubes, which were immediately centrifuged at 2700 rpm for 12 min. The resulting L-PRF clots were either compressed to collect exudate or cultured for 24h, 48h, 96h or 144h to obtain conditioned medium (CM). The morphology of L-PRF was characterized via electron microscopy and by performing immunostainings for CD41, fibrin and fibronectin. Next, an antibody array and ELISA was performed on exudate and CM to analyze the release of growth factors by L-PRF. Finally, we examined the effect of L-PRF on cell survival and neurite outgrowth by culturing rat DRG neurons under serum deprived conditions, and stimulating them with various concentrations of exudate and CM.

RESULTS & DISCUSSION: L-PRF consists out of two definable domains: a fibrin-rich zone that contains clusters of activated platelets and a leukocyte-rich area. It is a porous scaffold formed by fibrin fibers that also colocalize with fibronectin. Secretome analysis revealed that L-PRF contains many growth factors such as nerve growth factor, vascular endothelial growth factor, platelet-derived growth factor, and brain-derived neurotrophic factor, which are slowly released from the clot (n = 4-6). Moreover, neurite outgrowth and survival of DRG neurons was significantly increased by L-PRF CM in a dose-dependent manner (n = 6, p value < 0.01).

CONCLUSIONS: L-PRF slowly releases growth factors that support neuronal cell survival and stimulate neurite outgrowth. L-PRF is an autologous biomaterial that has several advantages in terms of biocompatibility and safety. It can be easily obtained from the patient’s own blood which makes it ideal in clinical applications. Our findings indicate that L-PRF may be suitable as a scaffold for nerve repair but this will be evaluated in future experiments.

INTRODUCTION: Photochemical crosslinking is advantageous due to temporal and spatial control over the gelation [1]. These advantages allow to prepare size and shape structured scaffolds using light processing techniques [2]. Hyaluronan (HA) is an important structural component of ECM. Therefore it is a suitable scaffolding material. But native HA does not form a gel nor support cell adhesion. Therefore it requires chemical modification according to the special demands of a particular application [3]. In this work we prepared cell-adhesive and covalently crosslinked hydrogels of HA suitable for advanced tissue engineering applications.

METHODS: Hydroxyphenyl RGD oligopeptides were synthesized by solid phase synthesis and conjugated with oxidized HA via reductive amination. The structural characterization of the derivatives was elucidated by NMR and Mw by Secmalls. The hydrogels were prepared from the precursor PBS solutions (1-3% w/v) with riboflavin as a photosensitizer using LED source (1.3-26.3 W/cm², 445 nm). Viscoelastic properties of the hydrogels were analyzed by AR-G2 rheometer using strain sweep mode. The swelling ratio of the samples was analyzed in PBS at r.t. Cell adhesion (3T3 fibroblasts, 20000 cells/well) was monitored microscopically and evaluated by ATP test.

RESULTS & DISCUSSION: Two adhesive derivatives of HA (RGD, RGD-Ahx) with DS = 4.5% and Mw = 396 kDa, 370 kDa were synthesized. They differed by the steric accessibility of a crosslinkable hydroxyphenyl group, which was increased in RGD-Ahx by the introduction of 6-aminohexanoic acid spacer. Both derivatives were subjected to photocrosslinking and the effect of material and process parameters on the gel properties was examined. The sterically less hindered RGD-Ahx provided 60% stiffer (G’ = 160 Pa) and 20% less swelled hydrogels (Qₑ = 80%). The optimal crosslinking conditions in relation to viscoelastic and sorption properties were determined: riboflavin conc. (8.7 µg/ml), polymer conc. (10 mg/ml), light intensity (13.2 W/cm²) and irradiation time (60 s). 2D cell assays clearly showed the difference in adhesion between both RGD derivatives and a negative control without RGD sequence.

CONCLUSIONS: This work showed efficient and light controllable preparation of the functional HA scaffolds.

INTRODUCTION: Dysfunctional salivary glands (SGs) caused by diseases or therapeutics may lead to serious clinical illness related to xerostomia.  
Cell therapy based on autologous progenitor cells are thus regarded as efficient and feasible solution. When SG progenitor cells are prepared to form salispheres, the spheroid-like structures, cavitation occurs during in vitro cultivation, which hampers their stemness. The study aims to explore the ways of regulation spheroid cavitation formation.

METHODS: The murine submandibular glands (SMGs) were retrieved from the adult mice, and prepared for salisphere formation. 
Fabrication of chitin biomaterials in distinct forms was performed as the methods previously reported. The change of salisphere phenotypes and the properties of cellular organization, stemness, and differentiation potentials were analyzed.

RESULTS & DISCUSSION: When the salispheres were cultured in the environment fabricated with chitin biomaterials, their numbers and the sizes increased. However, the incidence of cavitation was not affected. The effect was facilitated by high concentrations of chitin biomaterials, and fabricated as hydrogels. The salispheres were regulated in either intercellular interaction, or polarization to maintain the spheroid structure. The stemness properties of culture salispheres were preserved as well by showing characteristic features. The results demonstrated that the phenomena of spheroid cavitation of the salivary gland progenitor cells could be regulated by fabricated biomaterial environments, which helped to maintain the original properties of salispheres during in vitro preparation.

CONCLUSIONS: The data presented in the current study confirmed the advantages of applying biomaterial-fabricated culture environment to regulate the spheroid cavitation of salispheres during in vitro preparation.

INTRODUCTION: Hydroxyapatite (HAP, Ca_{10}(PO_{4})_{6}(OH)_{2}) is an inorganic component of bones and teeth. Hydroxyapatite possesses exceptional biocompatibility and bioactivity properties with respect to bone cells and tissues, probably due to its similarity with the hard tissues of the body. Nowadays hydroxyapatite is one of the most often applied bio-nanomaterials, e.g. in bone implants, scaffold layers, drug delivery agent, dental materials. Various processes for the preparation of HAP powders have been developed in the past [1-2].

METHODS: Hydroxyapatite nanopowder were synthesized by hydrothermal synthesis using microwave reactor MSS2 (Microwave Solvothermal Synthesis). The starting materials include pharmaceutical grade substrates: calcium hydroxide Ca(OH)_2 and orthophosphoric acid H_3PO_4 as substrates to obtain ceramic nanoparticles.

RESULTS & DISCUSSION: Obtained nanoparticles have average grain size in range of 8 - 45 nm. Thanks to a wide variety of grain size crystallinity it can be used in different application depending on desired resorption time of hydroxyapatite. The water is the single byproduct. Nanopowder has been characterized by several methods: X-ray diffraction (Phase Purity), SEM (morphology), BET (Specific Surface Area) and helium pycnometry (Skeleton Density).

CONCLUSIONS: Microwave synthesis allows easily and precisely control the grain size of nanoparticles. The mean grain size was controlled by synthesis conditions, such as time, pressure and temperature. Obtained hydroxyapatite is similar to the bioapatite.

ACKNOWLEDGEMENTS: This work was carried out in the Nanoligabond - Artificial tendons and ligaments fixation to bone tissue using nanotechnology approach - project financed by the European Regional Development Fund.

INTRODUCTION: With the advancement of digitalization and computer programming, image processing has become the latest tool to understand and quantify pore size, pore size distribution, porosity and microstructure of bio-aggregates in tissue-engineered scaffolds. Techniques available to analyse the microstructure of scaffolds include optical light microscopy, scanning electron microscopy, X-ray spectroscopy and field emission scanning electron microscopy. To quantify these micro-structures post microscopic analysis very challenging. Different image processing softwares like MATLAB, ICY, Avizo, Image Pro are available however, these programes are widely us ed to quantify pores over small sample areas with homogenous pore structure. The analysis becomes difficult when the size of the scaffolds increases (>16 cm2) and if the pore distribution is gradient.

METHODS: In this study, we present a method using ImageJ software to quantify pore size distribution of porous scaffolds with gradient porosity distributed over an area of 1 – 100 cm2 by utilising laser scanning confocal microscopy images.

RESULTS & DISCUSSION: A macro was created in ImageJ to test this method. A plugin called tubeness is used to perform the analysis. After tubeness processing to identify pore boundaries, images are thresholded then skeletonized. A watershed is run to separate overlapping pores, before measurement of pore area and shape descriptors. Using this method, pore distribution of a fibrin-alginate scaffold (49 cm2 > 1x108 pixels) was quantified within three minutes on a standard PC and measured over 227,000 pores.

CONCLUSIONS: Such tools offer the potential of repeatability, accuracy and effectiveness in data quantification which will be valuable for quality control during scaffold manufacturing processes.

INTRODUCTION: To successfully commercialize tissue engineered scaffolds it is essential to have a complete understanding about the specifications of the product. Scaffolds are extensively used as structural support to boost the function of damaged tissue in the field of tissue engineering and regenerative medicine (TERM). The complex structures and material properties result in distinct challenges with regard to analyzing and assessing the behavior of these materials. Imaging technologies have been widely used as a central tool in the field of TERM. Conventional methods such as histological and immunohistochemical techniques have been used to accumulate data on the engineered scaffolds but have failed to provide accurate information since they are invasive and can be used only on small samples rather than the entire scaffold. Imaging techniques should maintain the natural state of the material, should be quantitative, and allow three-dimensional (3D) analysis.

METHODS: To compare the structural features of a porous 3D 10*10 cm fibrin-alginate dermal scaffold different techniques ranging from scanning electron microscopy, atomic force microscopy, laser scanning confocal microscopy (LSCM), microCT, two photon microscopy, wide field microscopy and light microscopy were used.

RESULTS & DISCUSSION: Our results suggest that apart from LSCM, all the other techniques either altered the structure of the scaffold or could only visualize a small area and were time consuming. LSCM visualized the entire area of the scaffold (10*10 cm) in its natural state within 90 minutes at a high resolution, collecting multiple images in digital form from serial sections and finally representing the 3D structure of the scaffold.

CONCLUSIONS: This study discusses the difficulties involved in imaging 3D porous scaffolds and highlights the advantages and validity of LSCM.

ACKNOWLEDGEMENTS: This work was supported by the Restoration of Appearance and Function Trust (RAFT, UK, registered charity number 299811) and Smart Matrix Limited.
Silk fibroin and argentine clays for bone reconstruction: a novel hybrid material for bones
E. Bertoli¹,², V.E. Bosio²
Presenting Author: Valeria E. Bosio, vbosio@gmail.com
¹Theroretical and Applied Physico-Chemical Research Institute (INIFTA), National University of La Plata & CCT-CONICET La Plata, Bs. As., Argentina ²Biomaterials in Tissue Engineering Lab (BIOMIT), CINDEFI, University of La Plata & CCT-CONICET La Plata, Bs. As., Argentina

INTRODUCTION: Reconstructed Silk Fibroin (SF) from Bombyx mori is a biopolymer with biodegradability and biocompatibility for long-term medical implants. The versatility of this material for different structures and the possibility to be degraded with the time shows an advantage to rebuild damaged bones by Tissse Engineering (TE). However, a biomimicry of natural 3D bone structure made with silk needs to be mechanically reinforced. Herein, we ventured to developing a hybrid material with Montmorilonite (MMT), a natural clay from argentine environments, and SF, assessing the influence of these clays in the already known silk porous structures.

METHODS: Silk porous sponges were prepared by salt-leaching method following previously reported protocol [1] with some modifications. NaCl salt was sieved with metal mesh to obtain particle size distributions between 500 and 590 µm and added into SF aqueous solution (with or without Polyvinyl Alcohol (PVA), Alendronate (Alen) or MMT at a 2:1 (w/v) ratio), in tube-shaped containers. Deposition and inclusion methods were used to add MMT to the SF scaffolds. After that, scaffolds were drying at room temperature for 2 hs without stirring before their stored. Characterization of the new materials was carried out by SEM, FTIR, TGA, DSC, Compression resistance analysis & Encapsulation of deformable liposomes loaded with fluorescein.

RESULTS & DISCUSSION: All the SF-based scaffolds containing PVA, Alen or MMT presented significant increase (p < 0.001) of compression resistance with better results when MMT was present. FT-IR, TGA/DSC analysis suggest interactions between PVA and MMT with the SF correlated with a significant increase in the thermal stability of the hybrid materials compared with SF scaffolds. To evaluate the capacity of the hybrid scaffolds of loading/release cargo molecules during bone tissue regeneration process, deformable liposomes with fluorescein as model drug were included and studied in the systems, showing the capability of these materials to load and release drugs without loosing the structure and mechanical properties.

CONCLUSIONS: The results illustrate the beneficial effect of argentine natural MMT to enhance the properties of SF porous materials to be used as bone scaffolds for TE.

ACKNOWLEDGEMENTS: Financial support was received from CONICET and ANCyT.

INTRODUCTION: Amniotic Epithelial Cells (AEC) represent an emerging source in stem cells. However, AEC regenerative potential can be largely affected by the in vitro amplification. In order to standardize the AECs-based regenerative protocols, an advanced NGS approach of ovine cell characterization has been used to compare the transcriptome of 3 passages amplified oAEC obtained under standardized conditions (CTR) or by adding progesterone (P4) in order to preserve the epithelial native phenotype during expansion.

METHODS: The transcriptome profile has been performed by RNA sequencing (NextSeq500 Illumina platform). Differentially Expressed Genes (DEGs), identified using Tophat2-Cufflink2 pipeline [2], were by in house developed scripts to obtain enriched Gene Ontology (GO) terms and pathways.

RESULTS & DISCUSSION: The transcriptional landscape profiles showed 495 and 753 DEGs in CTR and P4, respectively, belonging to 3 main enriched GO-modules. In order to identify the mechanisms controlling biochemical pathways, we firstly derived a gene-gene network from DEGs. The networks were analyzed to detect both local and general hubs, which represent most connected nodes. They were compared to the bottleneck nodes that play a key role in controlling information throughout the networks. Integrating expression levels into the so obtained controlling structure (hubs, bottlenecks, DEGs), we identified a pattern of genes (listed in Figure1) characterizing the two oAECs transcriptomes.

CONCLUSIONS: For the first time, we described the whole transcriptome portrait of oAECs by using RNA-seq. The results clearly defined most biological processes and molecular pathways having a key-role in the two morphologically different oAECs. We, also, provided useful information to understand essential mechanisms involved in tissue regeneration. This approach can suggest a research framework in sheep, considered a consolidated model organism in regenerative medicine [3] filling lacking of information about the ovine genome and gene sequences.

INTRODUCTION: Human platelet lysate (hPL) arose as a xenogeneic-free alternative to FBS to be used as a supplement for expansion of human mesenchymal Stem Cells (MSCs) used in clinical applications. The use of the first generation Hpl involves the addition of heparin to the cell culture media to prevent clotting. Heparin is purified and refined from swine according to cGMP methods and is one of the most widely used drugs in humans. hPL with heparin (PLTMax®) has been used all over the world for more than 30 clinical trials. There has been no overt requirement for removal of heparin. However; some quality systems have requested its removal or replacement from cell culture processes in an effort to remove all xenogeneic components.

METHODS: To eliminate the need for heparin addition, Mill Creek Life Sciences developed PLTGold®, a step forward in the evolution of hPL. PLTGold® contains all the growth factors and proteins necessary for cell growth, but with reduced turbidity and no clot formation. Adipose derived and bone marrow derived mesenchymal stem cells (MSCs) were grown in media supplemented with either PLTMax® or PLTGold®. Growth kinetics, phenotype and capacity to undergo differentiation were compared for cells grown in each medium.

RESULTS & DISCUSSION: The chemical (pH and Osmolality) and biochemical analysis (Total protein content) performed for PLTGold® showed values comparable to those obtained for PLTMax®. MSCs grown in media supplemented with PLTGold® maintained the characteristic healthy MSC phenotype, as observed for cells grown in media supplemented with PLTMax®. The analysis of growth factors in PLTGold® revealed values that fell within the reference range established for PLTMax®. Real time imaging of cell growth using PLTGold® as a media supplement to grow adipose-derived and bone marrow derived MSCs showed increased cell growth kinetics (reduced cell doubling time) compared to cells grown in media supplemented with FBS or Human AB Serum. The performance of PLTGold® was comparable to the original hPL PLTMax®. After long term expansion of adipose derived and bone marrow derived MSCs in media supplemented with PLTGold®, both types of cells still maintained multipotency, with capacity to undergo adipogenesis, chondrogenesis and osteogenesis.

CONCLUSIONS: We report here PLTGold®, a new Human Platelet Lysate with the following characteristics: Xenogeneic free; Heparin-free; Unfractionated; Clot-free; Contains all the growth factors present in PLTMax®; Performance standards are similar or better than the original hPL PLTMax®. These characteristics make PLTGold® an ideal candidate to grow MSCs under cGMP conditions for use in the clinic.
In vitro expansion of human primary endothelial cells for clinical use using PLTGold® human platelet lysate
V. Alonso-Camino¹,², W. Mirsch¹

INTRODUCTION: Stem/progenitor cell based therapy is a leading strategy in regenerative medicine as reflected by the large and ever growing number of clinical trials indexed. The prospective use of exogenous endothelial cells to promote tissue repair is gaining attention in particularly in applications of regenerative medicine in which vasculogenesis plays a critical role. Some examples include large area wound healing, repair of the ischemic heart, vascular transplant and organ recellularization. In addition, as cells therapy progresses, combination cell therapies will likely play a bigger and more important role as tissue and organ engineering demonstrate more promise. To date, media available in the market to grow endothelial progenitor cells or endothelial primary cells are not GMP compliant or contain xenogeneic elements such as fetal bovine serum (FBS) or even bovine brain extract (BBE). However, the use of animal serum containing products to grow cells that will be used for clinical applications involves a series of risk factors ranging from immunogenic responses against exogenous antigens to the transmission of diseases. For this reason, there is a lack of available resources to support the use of endothelial cells in translational medicine.

METHODS: To determine if we could obtain a cGMP complete medium to grow endothelial cells, we supplemented EndoGo™ XF Medium (Biological Industries) with 5% PLTMax® or 5% PLTGold®. This combination was used to grow human umbilical vein endothelial cells (HUVEC) in comparison with the main product available in the market to grow endothelial cells. This competitor medium contains 2% Fetal Bovine Serum (FBS) and Bovine Brain Extract (BBE).

RESULTS & DISCUSSION: HUVEC grew rapidly in the EndoGo™ XF + PLTMax® combination (with an average doubling time of 26h) and demonstrated improved growth rate compared to the competitor medium. HUVEC maintained their typical endothelial cell morphology throughout the experiment. Besides the differences in cell growth between both products, cells grown in the competitor medium went into senescence and started detaching from the plate before reaching confluence, whereas cells grown in EndoGo™ XF + PLTMax® kept dividing even after reaching confluence. To eliminate the need for heparin addition, Mill Creek Life Sciences developed PLTGold®, a step forward in the evolution of hPL. PLTGold® is xenogeneic-free, Heparin-free, unfractionated and clot-free. Growth of HUVEC in EndoGo™ XF + 5% PLTMax® was compared with growth in EndoGo™ XF + 5% PLTGold®. The average cell doubling times obtained for medium supplemented with PLTGold® was 28h compared to the average of 26h obtained for PLTMax®. However, even when growth was slightly slower in EndoGo™XF supplemented with PLTGold® compared to the same medium supplemented with PLTMax®, cells continued exponentially growing until reaching 100% confluence without any indication of senescence or cell death as opposed to what happened when using the competitor medium containing FBS and BBE.

CONCLUSIONS: EndoGo™ XF + PLTGold® is the only completely xenogeneic-free and cGMP compliant medium available in the market to grow human endothelial cells. It also demonstrated improved growth rate compared to other media commercially available.
μυκοαδησική oromucosal slowly disintegrating bilayered patch with octenidine for oral ulcers treatment
V. Štěpánková1, J. Chmelař1, V. Velebný1
Presenting Author: Veronika Štěpánková, veronika.stepankova@contipro.com

INTRODUCTION: Oral ulcers are common, with an estimated prevalence of 4% in the world. Active substances are applied as topical pastes, gels or mouthwashes [1]. Disadvantages of these mentioned forms are their limited time of contact with the ulcers and the need to avoid drinking and eating for several tens of minutes. The aim of our work was to develop a bilayered mucoadhesive slowly disintegrating patch containing an antimicrobial agent octenidine that would cover the ulcer for at least one hour and allow fluid intake.

METHODS: Mucoadhesive films containing hydroxypropyl methylcellulose (HPMC) were prepared by solution casting. Parameters to select the final composition were visual evaluation of the solutions and fabricated films, their thickness and homogeneity, and evaluation of mucoadhesive properties. Active layer was prepared in the form of a lyophilizate from native hyaluronic acid (1 MDa) and octenidine (OCT). HPLC analysis was used to evaluate the amount and homogeneity of OCT. Antimicrobial activity of the lyophilizate was tested using diffusion plate method. Bilayered patch was created by moistening one side of the lyophilizate and the film using 90% (v/v) isopropanol and putting them in contact. Pressure was applied for a few seconds and the patch was left to dry at elevated temperature. Its surface pH was measured. MTT assay was used to assess cytotoxicity effect. Each form and the final patch were subjected to GC analysis to determine residual organic solvent, TGA analysis to determine dry mass, determination of weight per square meter and dissolution in human saliva. Prepared bilayered patches were tested by volunteers. They were positioned onto different places in oral cavity.

RESULTS & DISCUSSION: Clear solutions and visually homogenous films without any precipitation were prepared from HPMC, Eudragit, Eurocert Ponceau 4R and glycerol (200:75:1:0.06 w/w). Specifically, HPMC K15M and E4M (1:3 w/w) were combined with Eudragit RL100 and RS100 (1:9 w/w). Prepared films were 85±10 μm thick and their weight per square meter was 110±10 g/m². The dry matter was 94±1 %. In vitro dissolution test performed in Petri dishes in the presence of human saliva showed no fragmentation, satisfactory mucoadhesive force and over an hour dissolution time of the film. Weight per square meter of hyaluronan and OCT in the lyophilizate were 50-60 g/m² and 0.03-0.04 g/m², respectively. Antimicrobial activity against selected bacterial strains was demonstrated. pH of moistened bilayered patch was around 5, which is in the limit (4 ≤ pH ≤ 8) for safe use in the oral cavity. The content of residual solvents was below the limit of 0.5% (w/w) and cytotoxicity was excluded. In vitro dissolution tests of complete patches showed no difference compared to films tested alone, but the in vivo test revealed faster dissolution, detachment of the film from the active layer and subsequent adhesion of the film to other parts of the oral cavity.

CONCLUSIONS: Bilayered patch was successfully prepared and in vitro testing proved its safety. In vivo test by volunteers revealed the need to improve the cohesion of the layers and to increase hydrophobicity of external side of the film to prevent unspecific adhesion.

INTRODUCTION: Peripheral nerves are delicate organs which are frequently affected by traumatic injuries. Currently, nerve autograft is considered as the gold standard technique to repair critical nerve gaps with variable success rate [1]. Over the recent years several tissue engineering approaches demonstrated promising results and point out the potential usefulness of tissue engineering in peripheral nerve repair. The aim of this study was to create and evaluate a fibrin/agarose and adipose stem cell-based bioartificial substitute in peripheral nerve repair. Furthermore, the peripheral nerve regeneration profile was determined by using functional and histological quality controls.

METHODS: For this in vivo study, 20 adult male Wistar rats were used. Under general anesthesia a segment of 10-mm was removed from the left sciatic nerve of 15 animals. Defects were repaired by using nanostructured fibrin/agarose hydrogels containing cells (Nano) [1], NeuraGen® conduits filled with Nano (Coll-Nano) and autografts (n=5 each). Furthermore, 5 animals were used as native controls. After 12 weeks, animals were subjected to pinch test, toe-spread test and electromyography. After 14 weeks, animals were euthanized for histological and morphometry analyses of implanted grafts and distal muscles [2].

RESULTS & DISCUSSION: Functional analyses showed slight differences between engineered strategies as compared to autografts, especially for the use of Nano substitutes. Electromyography revealed clear signs of reinnervation of distal muscles in Auto and Nano groups which were significantly superior to Coll-Nano group. Histology demonstrated an active nerve tissue regeneration process at the middle portion of implanted grafts, being these results comparable between Auto and Nano groups and both superior than Coll-Nano group. Muscle morphometry revealed less percentage of weight and volume loss in Auto group followed by Nano and finally Coll-Nano group respectively, and differences were confirmed by muscle histology.

CONCLUSIONS: In this in vivo study we demonstrated that nanostructured fibrin/agarose hydrogels containing adipose stem cells can promote functional recovery, muscle reinnervation and tissue regeneration in a comparable manner to autograft technique. However, future studies are needed to demonstrate the potential usefulness of these substitutes in the repair of critical nerve defects.

INTRODUCTION: 3D cellular aggregate generation on agarose chips is a useful cell culture alternative in tissue engineering approaches. The aim of this study was to generate, characterize and compare the structural and biological properties of human hyaline and elastic cartilage-derived chondrocytes spheroid aggregates as potential alternative for cartilage tissue engineering.

METHODS: Human hyaline and elastic cartilage-derived chondrocytes were isolated from cartilage biopsies. Tissue samples were in collagenase and cells were obtained by centrifugation. Spheroid aggregates were generated by seeding 2.5 x 10⁵ cells in agarose microchips containing approximately 1250 micro-wells with an average diameter of 400 μm [1]. The spheroid aggregates were controlled daily by phase contrast microscopy analysis. Cell viability, proliferation and cell damage were determined by Live/dead, WST-1 and DNA release methods; structure and histological properties were analyzed at 4, 7, 14, 21, 28 days of ex vivo culture.

RESULTS & DISCUSSION: Chondrocytes from elastic and hyaline cartilage were able to self-assemble and form stable aggregates from day 3 onward. Viability assessment revealed high cell viability and proliferation rate in both types of aggregates over the time. Histology revealed a uniform cell distribution pattern in each, but hyaline-derived aggregates resulted more compacted than elastic-derived structured, which showed a looser pattern. Histochemistry confirmed the progressive synthesis over the time of acid proteoglycans in both types of aggregates.

CONCLUSIONS: This study demonstrated that human hyaline and elastic cartilage-derived chondrocytes are a suitable cell source for the generation of stable and functional aggregates. These chondrocyte-based aggregates could be promising alternatives to generate functional and biomimetic cartilage bioartificial models for tissue engineering applications.

IFN-γ primed mesenchymal stem cells from paediatric patients (pMSCs) exhibit immunomodulatory abilities towards allogeneic B and T cells

V. Palomares Cabeza¹,²,³, M.J. Hoogduijn², R. Kraaijeveld², M. Franquesa⁴, E. Wolvius¹, E. Farrell¹, P. Brama³

INTRODUCTION: Mesenchymal stem cells from paediatric patients (pMSCs) are an attractive cell source in regenerative medicine, due to their higher proliferation rates and better differentiation abilities compared to adult MSCs (aMSCs) [1]. We have previously characterized the immunomodulatory abilities of undifferentiated pMSCs on T cells under co-culture [1]. Luk et al. reported that undifferentiated aMSCs can inhibit B cell proliferation and maturation under inflammatory conditions. In this study, we aim to clarify the immunomodulatory effect of pMSCs towards B and T cells in an inflammatory microenvironment.

METHODS: Bone marrow derived pMSCs or aMSCs were primed for 3 days with 50 ng/mL of IFN-γ. To analyse the interaction between pMSCs and T cells under inflammatory conditions, CD3/CD28 stimulated peripheral blood mononuclear cells (PBMCs) were co-cultured with primed or unprimed pMSCs. To investigate B cell responses, quiescent B cells obtained from spleens by CD43 negative selection were stimulated with anti-IgM, anti-CD40, IL-2 and co-cultured with either IFN-γ primed or unprimed pMSCs or aMSCs. The immunophenotype of pMSCs upon IFN-γ stimulation, and T and B cell proliferation after 5 and 7 days of co-culture, respectively, were analysed by FACS. IgG production by B cells was determined by ELISA.

RESULTS & DISCUSSION: pMSCs upregulated the expression of HLA-ABC, HLA-DR and the co-stimulatory molecules CD80 and CD86 upon IFN-γ priming. IFN-γ addition on pMSCs did not seem to further decrease the proliferation rates of CD4⁺ nor CD8⁺ stimulated T cells compared to unprimed pMSCs. IFN-γ primed pMSCs but not unprimed pMSCs strongly inhibited naïve (CD19⁻CD27⁻), memory (CD19⁺ CD27⁺), and total B cell proliferation. Antibody-producing plasmablast (CD19⁺CD27hi, CD38hi) formation and IgG production was also significantly inhibited by IFN-γ primed pMSCs compared to unprimed pMSCs.

CONCLUSIONS: Collectively, these results show that pMSCs have immunomodulatory effects upon the adaptive immune response which can be influenced by the inflammatory microenvironment. This knowledge can be useful in regenerative medicine in tailoring the pretreatment of pMSCs to best modulate the immune response for a successful implant engraftment and avoidance of a strong allogeneic immune response.

INTRODUCTION: Mechanical articular cartilage trauma are one of the most common in the knee joint injuries and makes up 35 - 55%. Condylar fractures of the knee joint in most cases provoke the development of deforming arthrosis. Current techniques to repair injured cartilage cannot completely regenerate the natural cartilage functions. In recent years mesenchymal stem cells (MSCs) have been proposed as a potential regenerative cell therapy for patients with cartilage damage. Genetic modification of MSCs to express certain anti-inflammatory cytokines can significantly enhance their regenerative potential. The purpose of this study was to evaluate the effectiveness of human MSCs overexpressing interleukin-10 on the model of acute lesion of the knee cartilage in rats.

METHODS: Human MSCs were isolated from umbilical cords by explant method. At the second passage cells were characterized by morphology, MSCs surface markers and trilineage differentiation. hIL-10/GFP-encoding plasmid was created and umbilical cord MSCs were transfected using TurboFect. MTT assay was applied to measure cytotoxicity of poliplexes at 24h post transfection. Transfection effectiveness of polyplexes have been evaluated by flow cytometry of 48 h post transfection culture, and quantitative green fluorescent protein expression was calculated against recombinant eGFP by Bio-Tek Synergy HT. IL-10 concentration was determined using enzyme-linked immunosorbent assay “Interleukin-10 - IFA-BEST ” Kit in conditioned serum-deprived culture supernatants of transfected MSCs after 48 hours of culture. Intraarticular injections of 1x10^5 MSCs-IL-10 were performed in rats with mechanical damage of articular cartilage. Histological and biochemical methods are used to assess the therapeutic effects of genetic modified MSCs.

RESULTS & DISCUSSION: Transfected MSCs have shown high viability (94-96%). More than 95% of transfected MSCs were positive for stem cell markers (CD73, CD90, CD105) and negative for CD34, CD45. The results of ELISA revealed that considerable amounts of human IL-10 (640 pg per1x10^5 cells for 48 h) was secreted from hMSCs/IL-10, while for naive hMSCs its own IL-10 synthesis is much lower - 7 - 9 pg per 10^5 cells for 48 h. Histological analysis of damaged tissues after transplantation showed that the formation of mature chondrocytes, pronounced endosteal and periosteal chondrogenesis, the formation of mature endosteal and periosteal cartilage tissue in rats that were transplanted with MSC-IL10 occurred in a much shorter time than in control animals. As well as in contrast to the untransplanted control group there was no excessive production of the ossetizing matrix and there were no dystrophic changes of chondrocytes and chondroblasts in experimental rats.

CONCLUSIONS: Intra-articular injection of human MSCs with enhanced synthesis of anti-inflammatory cytokine IL-10 leads to accelerated recovery of damaged cartilage tissue.
A novel anti-adhesion material using LYDEX

INTRODUCTION: Adhesion of living tissue after surgery not only causes adhesion bowel obstruction, but makes surgery difficult due to poor visual field and bleeding during reoperative surgery. It is also said to cause a number of sequelae such as chronic abdominal pain and infertility [1-3]. Herein, in order to prevent adhesion living tissue, we ventured to evaluate the possibility of application as an adhesion prevention material using a novel self-degradable medical adhesive "LYDEX®" consisting of aldehyde dextran and succinic anhydride treated poly-L-lysine.

METHODS: We evaluated the prevention efficiency from adhesion of the powder type LYDEX in an adhesion model (the intestines). Sprague-Dawley Rat with with body weights (300-310g) were used for the experiment. Width 2.5cm four quarters, about 1mm depth are exfoliated, and the model is produced by filling in addition, the lesion with the burn by the electric knife, after median incision, left side peritoneum and tunica muscularis of rat. The affected part was washed at Ringer’s solution after defect creation, and it allowed to stand it for 2 minutes until it applied and hardened LYDEX®. After that, Ringer's solution washed the affected part, it made the closed abdomen. Two weeks later, the abdomen was incised, and the state of adhesion was evaluated with three steps of score.

RESULTS & DISCUSSION: The result of the prevention from adhesion carried out by this research is shown in Fig.1. In this figure, we compared various LYDEX®, a SepraFilm, Fibrin glue, and an untreated score. The adhesion score of Fibrin glue was high to the same grade as untreated. In addition, the error bar of SepraFilm was large and it was high-scoring. On the other hand, the score of LYDEX® is low and the Powder type had the lowest score. It was shown that LYDEX® has a SepraFilm of an existing product and the adhesion prevention efficacy more than equivalent also in which type.

CONCLUSIONS: As a result of verifying adhesion prevention performance by applying LYDEX® and ready-made product to an animal model, the possibility of application as an anti-adhesion material was confirmed.

INTRODUCTION: The development of inexpensive and simple analytical tools is of practical significance for biological sample analysis. There is still no simple and inexpensive method to measure dopamine in tissues.

METHODS: This work reports the development of a simple and cost-effective electrochemical sensor modified with multi-walled carbon nanotubes (MWNTs) and covered with filter paper for selective and sensitive detection of dopamine (DA) extracted from animal tissues (Fig. 1).

RESULTS & DISCUSSION: The response to DA occurs at a relatively low potential (0.43 V vs. Ag/AgCl) and is not interfered by Noradrenaline (NE) and 5-hydroxytryptamine (5-HT). The influence of electrode area and the amount of assembled MWNTs on the analytical signals were studied. Under optimized experimental conditions, the amperometric response to DA is linear in the 2.5×10^{-8} M to 1×10^{-6} M concentration range, and the detection limit is 5 nM (at a signal-to-noise ratio of 3). The method was further applied to quantify DA in the brain tissue and tendon tissue of rats (Fig. 2). In comparison to conventional methods, the proposed method is simple, rapid and inexpensive. More importantly, the developed sensor is supposed to be a single-use disposable device and electrodes were prepared “as new” for each experiment.

CONCLUSIONS: In our perception, this approach provides an effective way to quantify DA and therefore has a large potential in the field of DA-related diagnostics.

Figure 1: (left) A disposable indium-tin-oxide electrode modified with carbon nanotubes was applied for the sensitive detection of DA extracted from animal tissues. Figure 2: (right) (A) DPV curves of different volumes of DA(0 M, 5×10^{-7} M, 10^{-6} M, 2.5×10^{-6} M, 4×10^{-6} M, 5×10^{-6} M) was added to the diluted brain tissue sample (PH=6.0), Inset: Plot of the peak current against the concentration of DA. (B) DPV curves of the diluted tendon tissue sample (PH=6.0) (a). DPV curves of different volumes of 5 μM NE (b) and 5 μM 5-HT (c) was added to the diluted brain tissue sample3 (PH=6.0) (n=3).

INTRODUCTION: There are different types of cartilage in the body. Some are stable, such as in articular joints and others are unstable, as in the growth plate and transform into bone. These types of cartilage differ in the invasion by blood vessels that mark the onset of endochondral ossification (EO). Another hallmark of transient cartilage (TC) is chondrocyte hypertrophy, which can be found in a specific zone of the growth plate, the only one invaded by blood vessels. This is induced by secreted factors. Here we look at the impact of selected factors on the angiogenic potential of the secretome of TC.

METHODS: Candidate secreted angiogenic factors from cartilage were identified by comparison of microarray data of the different zones of murine growth plate [1] and gene enrichment analysis to screen for secreted angiogenesis regulating factors. We compared the identified factors with a human microarray that compared TC formed by bone marrow derived mesenchymal stem cells (MSC) with neonatal articular cartilage [2]. The secretome of 3D pellets of MSCs of 3 donors that were chondrogenically differentiated for 21 days [3] was collected and tested for angiogenic capacity with and without blocking the candidates. We performed different in vitro assays, the endothelial migration and proliferation assay as well as in vivo assays, the chick chorioallantoic membrane (CAM) assay.

RESULTS & DISCUSSION: We identified 8 factors as candidate angiogenic factors secreted by TC. Gene expression in chondrogenic MSC pellets compared to articular chondrocyte pellets by qPCR led to the selection of IHH and PAI1 as most interesting candidates due to their upregulation in TC. MSC derived CM showed a pro-angiogenic potential in the in vitro and in vivo assays. Blocking IHH or PAI1 in the CM further increased its proliferation and migration potential in vitro.

CONCLUSIONS: In the secretome of TC, both IHH and PAI1 had an anti-angiogenic effect, inhibiting mainly endothelial cell proliferation and migration. In conclusion, we provide evidence that IHH and PAI1 play a role in regulating blood vessel formation during EO.

ACKNOWLEDGEMENTS: This project is funded by EU’s H2020 research and innovation programme under MSCA No 721432 and partly by a grant from the NIH/NIBIB: 1P41EB021911 "CWRU”

INTRODUCTION: The extracellular matrix (ECM) is a complex network of a variety of proteins, proteoglycans, and other macromolecules, where it can provide structural and biochemical support such as cell adhesion, migration, proliferation, and differentiation. There has been especially growing interest in the cell-derived ECM (CECM) due to the potential of paracrine components secreted from specific cells, compared with its of tissue composed of various cells [1,2]. In this study, we have developed a new platform based on the bioactive CECM derived from human lung fibroblasts (WI-38) as a scaffold for wound healing.

METHODS: The CECM scaffolds obtained by WI-38 culture, decellularization and lyophilization. The structure and pore size of the scaffolds were characterized using scanning electron microscopy (SEM). The bioactive molecules such as proteins and growth factors in the CECM scaffolds were identified using immunofluorescence staining (IF), Western blotting (WB), and enzyme linked immunosassay (ELISA). Their potential contribution involved in wound repair was evaluated using in vitro cell study and a full-thickness cutaneous wounds in mice.

RESULTS & DISCUSSION: To confirm the decellularization process, DNA quantitation and DAPI staining of the CECM were examined. Decellularization resulted in almost complete removal of nuclei and DNA. Six major macromolecules, fibronectin, collagen (I, III, IV), laminin and elastin were identified using IF, WB, and ELISA. The ECM components were abundantly preserved. The CECM scaffolds have the open-porous microstructures with pore sizes ranging 50 µm to 300 µm. The results of cell study showed that the scaffolds were cytocompatible and stimulated cell proliferation. The quantity of CECM in the scaffolds study was considered to be effective biologically in further experiments using an animal models such as diabetic ulcers and burns.

CONCLUSIONS: The bioactive scaffolds based on CECM was successfully developed by decellularization method. The obtain results demonstrated that the CECM scaffolds could be extensively utilized in tissue engineering for clinical applications.

INTRODUCTION: Adipose-derived stem cells (ASCs) have been gaining fame mainly due to their vast clinical potential, simple isolation methods and minimal donor site morbidity. In particular endothelial cells present in SVF, which are isolated from adipose to obtain the local stem cells, are microvascular endothelial cells that are involved in angiogenesis, symbiotic healing, and inflammation, and have essential angiogenesis capabilities when repairing and rebuilding damaged tissue [1,2]. The aim of this study was a method for reliable isolation of human adipose-derived microvascular endothelial cells (HMVEC-A) has been developed and subsequently characterized in the expression of surface markers associated with endothelial cells.

METHODS: Human adipose-derived microvascular endothelial cells (HMVEC-A) were isolated from Adipose-derived stem cells in fresh human adipose-derived stromal vascular fraction (SVF). After enzymatic digestion to form a single cell suspension, SVF was cultured and ASCs were attached, and the supernatant was harvested to isolate HMVEC-A. And the separated HMVEC-A using anti-CD31 coated Dynabeads high purity culture, and confirmed typical endothelial cells showed cobblestone morphology, CD31, vWF, CD105, CD144, CD146 and eNOS, and normal function of the endothelium was confirmed by the Dil-Ac-LDL uptake measurement and measuring the capillary-like tubes in Matrigel.

RESULTS & DISCUSSION: This method has enabled the rapid isolation of viable cells to demonstrate a typical endothelial cobblestone morphology during incubation. Cells were confirmed positive for CD31, vWF, CD105, CD144, CD146 and eNOS. The cells were able to identify Dil-ac-LDL uptake and form a capillary-like tube structure when cultured in Matrigel.

CONCLUSIONS: In conclusion, microvascular endothelial cells isolated and cultured by the novel method showed high purity and characteristic of vascular endothelial cells. This method has developed a protocol that simplifies and economic isolation and cultures microvascular endothelial cells from adipose tissue while eliminating complex processes.

INTRODUCTION: Adjuvant chemotherapy has been widely used to prevent relapse of cancer after surgical resection of tumor [1]. However, the systemic drug delivery platforms have limitations for clinical translations such as rapid clearance, and systemic toxicity [2]. Therefore, the local delivery of nanoparticles (NPs) can enhance accumulation in tumor, increasing therapeutic effects. Especially, the spraying system allows the uniform placement of NPs onto tumor resection sites in a simple way. For efficient retention on target sites, the adhesion and dispersion properties of NPs are essential in spraying system. Here, we propose sprayable adhesive NPs using mussel adhesive protein (MAP) for effective site-directed cancer therapy.

METHODS: The MAP NPs were fabricated by electrospraying process. The surface adhesion of the MAP NPs was quantified using a Quartz Crystal Microbalance (QCM). For a pH-dependent release profile, the DOX-loaded MAP NPs (MAP@DOX NPs) in dialysis membrane were incubated in buffer of several pH, and then the amounts of released DOX were measured using a fluorescence spectrometer. In addition, in vivo anticancer effects of MAP@DOX NPs were investigated using a tumor xenograft mouse model administered by surgical spraying process.

RESULTS & DISCUSSION: The MAP NPs were successfully fabricated and achieved higher adhesiveness compared to BSA NPs. The MAP NPs were sprayed by using an air-pressured atomizer and exhibited high-throughput deposition without breakage of NPs. The MAP@DOX NPs efficiently released DOX in response to the acidic pH condition, and showed effective cytotoxicity on breast cancer cells. For the focal administration of NPs, the MAP NPs were surgically sprayed on tumor tissues and showed efficient retention on tumor sites via their adhesive property. Moreover, the MAP@DOX NPs were effectively inhibited tumor growth compared to free DOX and PBS groups, demonstrating that MAP NP-based spray system could achieve localized drug delivery, improving anticancer effects with a reduced systemic toxicity.

CONCLUSIONS: The sprayable adhesive NPs are expected to be a promising therapeutic strategy for localized adjuvant cancer therapy.

TGF-β1-induced Connexin43 promotes scar formation via the Erk/MMP-1/collagen III pathway

Y. Liu, X. Li
Presenting Author: Yi Liu, lililiuyi@163.com
Laboratory of Tissue Regeneration and Immunology and Department of Periodontics, School of Stomatology, Capital Medical University (CCMU), Beijing

INTRODUCTION: Wound healing can be divided into different phases. Timely initiation and cessation of these stages are the key to successful wound healing; otherwise, scar tissue will be present in the wounded area. Connexins (Cx) were confirmed to influence and regulate scar formation. The aim of the present study was to investigate the role of Cx43 in the scar formation process and the possible underlying cell signaling pathways.

METHODS: RT-PCR, western blot analysis, immunohistochemistry staining and immunohistofluorescence staining were performed to examine the expression of extracellular matrix components and key proteins of cell signaling pathways.

RESULTS & DISCUSSION: After injury, wounds in the buccal mucosa healed with no scar, whereas skin healed with an evident scar. TGF-β1 expression was gradually increased at the 5th day after injury, along with Cx43 expression, which was progressively increased in the skin and peaked at the scar formation stage. TGF-β1 and Cx43 expression in the oral mucosa was maintained at a low level. The high level of TGF-β1 increased p-Smad2/3 and then induced Cx43, whereas Cx43 overexpression antagonized the phosphorylation of Erk1/2, a downstream protein of Cx43, which affected MMP-1 synthesis. The MMP-1 deficiency led to Collagen III accumulation and facilitated scar formation.

CONCLUSIONS: We demonstrated that TGF-β1-induced Cx43 promoted scar formation via the Erk/MMP-1/Collagen III pathway.

Figure 1: Scar formation was more evident in the skin than the oral mucosa, TGF-β1-Induced Connexin43 Promotes Scar Formation via the Erk/MMP-1/Collagen III Pathway

INTRODUCTION: Advances in 3D hydrogel biomaterials, with bioprintable properties, provides new tools towards modeling the human blood brain barrier and neurovascular function. Due to the complexity of the brain structure, current monolayer transwell BBB models do not recapitulate the three dimensional (3D) micro-environment of the neurovascular unit, such as the cellular heterogeneity, anatomical size and shear stress conditions. To address these limitations, three-dimensional (3D) bioprinting using human induced pluripotent stem cell (iPSC)-derived brain endothelial cells (iBECs) holds immense promise for providing a rapid and robust approach for recapitulating the physiological cellular heterogeneity and structural complexity of the BBB in vivo. In this study, alginate and gelatin, two of the most common biomaterials with biocompatibility, biomimicry and mechanical integrities are employed as printable hydrogel materials to support iBEC attachment and viability.

METHODS: Sodium alginate and gelatin was dissolved in human endothelial serum free growth medium with 1% fetal bovine serum (EM) and combined to form a final concentration of 3 w/v% alginate 7 w/v% gelatin solution (A3G7). Pure alginate hydrogel (3 w/v%) was used as control. Human iBECs were derived as previously described [1] and mixed with the alginate and A3G7 solution to form bioinks with a cell density of $15.5 \times 10^6$ cells/mL. Bioink in the form of beads and film were formed by dispensing 200 ~ 500 µL of cell solution into a 24 well plate followed by adding a 60mM CaCl$_2$ solution to crosslink the bioink for 5 mins. Fresh media was added to each well and the plate was placed in an incubator at 37°C and 5% CO$_2$. The cell culture media was replaced every day and after 4 days of culture, samples were fixed in formalin and stained with WGA-FITC and Hoechst to visualize cell membrane and nuclei respectively.

RESULTS & DISCUSSION: Fluorescence analysis of WGA-FITC and Hoechst illustrated a significant increase in cell density and attachment of iBECs using alginate-gelatin A3G7 bioink compared to pure alginate. There were more visible areas of cell aggregation in the A3G7 which facilitated cell attachment and cellular viability.

CONCLUSIONS: These results demonstrate the beneficial effect of gelatin in functionalizing gelatin-based bioinks for improved cell attachment of iPSC-derived human brain endothelial cells. Optimization of hydrogels, with bioprintable properties, will enable more complex and physiological BBB modeling through deposition of layered 3D cell structures.

INTRODUCTION: Platelet-rich plasma (PRP) therapy is a new type of growth factor treatment for OA. It is a simple, safe, low-cost and minimally invasive method that provides a natural concentrate of autologous blood growth factors (GFs). In addition, mesenchymal stem cell (MSC) injection in conjunction with PRP might produce a better therapeutic effect due to the growth factor release effect of PRP and the tissue regeneration ability of MSC. In the study we would like to compare the PRP component difference among pure-PRP (P-PRP), leukocyte-poor PRP (LP-PRP) and leukocyte-rich PRP (LR-PRP) isolation system, and evaluate the efficacies of these PRP or PRP/MSC for the treatment of OA in in vitro system.

METHODS: Five kinds of culture conditions would be evaluated in the study including (I) damaged chondrocytes/PRP/bone marrow MSCs (BMMSCs) co-culture system, (II) damaged chondrocytes/PRP culture system, (III) damaged chondrocytes/BMMSCs co-culture system, (IV) damaged chondrocytes system and (V) normal chondrocyte control group. In system I and III, chondrocytes and BMMSCs were cultured on the bottom layer in the transwell, individually.

RESULTS & DISCUSSION: In this research, the results of complete blood count showed that all – the PRP groups showed less cell numbers in red blood cells and abundant cell numbers in platelets. In the leukocyte-rich PRP group, it showed that the isolated PRP containing more lymphocytes, monocytes, eosinophil and basophil than others. As for leukocyte-poor PRP group, it has only small amounts of lymphocytes. There was no significant difference in the growth factor content of PDGF-AB, TGF- and VEGF among these PRP isolation system.
In culture system, we found PRP/MSC co-culture system show synergistic pro-inflammatory performance on Day 1 and Day 3, especially in LR-PRP and LP-PRP groups compare to the damaged chondrocytes group. Only P-PRP groups showed significantly down-regulated inflammatory related genes such as IL-6, IL-1 and TNF- on Day 3, and significant different compare to the damaged chondrocytes group at Day1. In BMMSCs group, results showed that they performed a great anti-inflammatory ability compare to each PRP groups. Besides, the results of three kinds of PRP treated group (system II) were a little different to the system I. The LP-PRP treated groups showed a decreased in the inflammatory responses on Day 3 when comparing to the damaged chondrocytes groups.

CONCLUSIONS: To sum up, PRPs contained some leukocytes may not good for damaged chondrocyte recovery in OA treatment. Besides, when these PRP combined with BMMSCs also induce higher levels in inflammatory responses. Therefore, it seems that pure-PRP or BMMSC might be a better choice for OA patient use in the future.

INTRODUCTION: Successful cartilage regeneration has long been challenging. Cell sources of human chondrocytes are highly limited, and chondrocytes tend to dedifferentiate when they are heavily expanded in vitro. Upon the significant role of extracellular matrix (ECM) in cartilage regeneration, we have investigated chondrocyte-derived extracellular matrix (CHDM) substrates to proliferate human nasal septal chondrocytes (NSCs) and to keep them with chondrogenic potential.

METHODS: NSCs are cultured until confluence and then treated with 0.15% Triton X-100 and 10 mM NH₄OH (Sigma-Aldrich), then 50 U/mL DNase I and 2.5 µL/mL RNase A (Invitrogen) to obtain decellularized chondrocyte derived ECM (N-CHDM). To make soluble CHDM (S-CHDM), the N-CHDM was digested using 1 mg/ml pepsin (Sigma-Aldrich) in 0.01 N HCl, then treated with 0.1N NaOH for neutralization. NSCs (P5) proliferation on each substrate (TCP, N-CHDM, S-CHDM) was evaluated using cell counting kit-8 (Dojindo). The protein and gene expression of chondrogenic markers were also examined via immunofluorescence and q-PCR, respectively.

RESULTS & DISCUSSION: NSC shows distinct morphology, more focal adhesion (data not shown) and much better cell proliferation on N-CHDM. Cell differentiation was also notably different: more positive signals of collagen type 2 (Col 2) via immunofluorescence staining and significantly upregulated chondrogenic markers (Col 2, Sox9 and Aggrecan) expression on N-CHDM via q-PCR.

CONCLUSIONS: Current results suggest that on the N-CHDM, both proliferation and chondrogenic differentiation of NSC are beneficial, due mainly to the biophysical microenvironments of N-CHDM that are more natural for NSCs.

Figure 1: (A) Proliferation of NSCs on each substrate at 0, 2, and 4 day; (B) Immunofluorescence of Col 2 (green), F-actin (red) at 1 and 7 day; (C) Gene expression of chondrogenic markers (Col 2, Aggrecan and Sox9) via q-PCR. Statistical significance (*p<0.05, **p<0.01, ***p<0.001).

Advanced cardiac tissues from human embryonic stem cells by employing Layer-By-Layer and growth factor treatment

INTRODUCTION: Engineering cardiac tissues generated from human embryonic stem cells are promising for regenerative medicine, drug testing, and disease modeling. Generation of structurally and functionally similar cardiac tissue to the actual heart could allow efficient improvement of heart studies [1]. Here, we demonstrate a simple method to develop cardiac tissues by employing layer-by-layer (LBL) deposition and accordion-like honeycomb (ALH) patterning with the use of growth factors.

METHODS: 1x10⁶ cells of H9 (human embryonic stem cell) derived cardiomyocytes and cardiac fibroblasts with 400 ul of collagen type I gel are placed in a flat or honeycomb patterned mold, respectively, and centrifuged for 1 min. After 40 min of gelation, RPMI media (Gibco) with or without 20 ng/ml of FGF-4 (Peprotech), 200 ug/ml of ascorbic acid (Sigma Aldrich) were added, respectively, and changed every 2 days. Immunocytochemistry, real-time PCR, and confocal microscopy analysis were conducted by removing the cardiac patches from each mold at given time points.

RESULTS & DISCUSSION: The cardiac patches prepared by LBL and ALH show that the expression level of MLC2v (cardiomyocyte maturation marker) is 20 times higher than that of a control group without LBL and ALH. The analysis of their beating video provides the fact that LBL improves consistency of the beating rate by decreasing the variance of contraction and relaxation times among cell patches. ALH further enhances the beating properties by narrowing the variance when combined with LBL, but ALH by itself is not effective.

CONCLUSIONS: The result suggests that a simple method using LBL and ALH is highly beneficial to develop cardiac patches with consistent beating properties. The expression value of MLC2v restates that the method exponentiate the maturation of H9 cells into cardiomyocytes. Thus, our finding has an important implication for engineering functional cardiac patches in vitro and their use in the fields of heart related studies.

INTRODUCTION: The repair of peripheral nerve defects largely depends on engineered nerve grafts. There is still no satisfied materials combining hierarchical structure and electrophysiological property suitable for the peripheral nerve regeneration.

METHODS: In this work, silk was used as raw material, PPy/SF conductive composite scaffold was fabricated by employing 3D bio-printing and electrospinning together (Fig. 1). A 10-mm-long sciatic nerve gap in rats was bridged by PPy/SF to investigate whether PPy/SF conductive composite scaffold was suitable for neural tissue application.

RESULTS & DISCUSSION: Schwann cells can be attached to the surface of the scaffold to maintain their normal configuration-full, spindly and proliferate well on the PPy/SF scaffolds. The conductive composite tissue engineering scaffold facilitates the adhesion and growth of DRG. Immunochemistry (Fig. 2) demonstrated that these PPy/SF promoted peripheral nerve regeneration because electrospun aligned nanoporous SF fibers were responsible for their good hierarchical structure and deposition of PPy enhanced their electrophysiological properties.

CONCLUSIONS: The research provides a new method and idea for the construction of artificial nerve grafts, provides a preliminary research basis for the application of new conductive materials in the field of tissue engineering.

INTRODUCTION: Although pancreatic islet transplantation therapy is ideal for diabetes patients, several hurdles prevent it from becoming a standard treatment, including donor shortages and low engraftment efficacy. Insulin producing cells (IPCs) differentiated from stem cells is actively developing as a new islet source but the physiological function of IPC is still not enough to control diabetics in vivo. In this study, to improve the differentiation function of IPCs, we developed three-dimensional (3D) culture technique of IPCs using concave microwell.

METHODS: Human induced pluripotent stem cells (iPSCs) were differentiated into IPC using small molecules. The cells were maintained on vitronectin coated culture dish in TeSR-E8 media. Human iPSCs differentiated into IPCs through stages in the following order. For pancreatic differentiation, the cells were cultured in RPMI medium containing 1% B27 with 100 ng/ml human activin A and 3 μM CHIR99021 for 24 h (Step1), and then in RPMI medium containing 1% B27 with 100 ng/ml activin A for 48 h (Step2). Subsequently, the medium was replaced with Improved MEM Zinc Option medium containing 1% B27 with 1 μM dorsomorphin, 2 μM retinoic acid and 10 μM SB431542 (Step3). Cells were cultured for 7 days and then these media were replaced with Improved MEM Zinc Option medium supplemented with 1% B27 with 10 μM forskolin, 10 μM dexamethasone and 10 mM nicotinamide (Step4). To enhance differentiation function of IPCs, spheroids were prepared using PDMS concave microwell. For long-term culture, the spheroids were culture in the shaking incubator with a circular motion. The differentiation efficiency of spheroid was compared to 2D monolayer culture by gene expression, insulin secretion, glucose stimulated insulin secretion (GSIS), and histology.

RESULTS & DISCUSSION: In this study, iPSCs successfully differentiated into IPCs. We fabricated 3D IPC spheroids using concave microwell, which was possible to mass-produce spheroids of the desired size. The size of the spheroid was increased in proportion to the number of cells with narrow size distribution. The cells in IPC spheroid showed higher expression of beta cell related transcription factors and insulin genes than the cells from 2D culture. Also, IPC spheroid showed insulin secretion rate in a glucose dependent manner (GSIS index: 1.96±0.68) but IPCs from 2D plate showed no response in glucose concentration (GSIS index: 1.18±0.37). In immunocytochemistry staining, the 3D differentiated IPCs can assemble into an islet like spheroid structure. Insulin positive cells make a cluster in a core, which indicating the post maturation of pancreatic endocrine cells can be regulated by 3D culture condition.

CONCLUSIONS: Using concave microwell chip, IPC spheroids of desired size were fabricated with mass production. Because 3D spheroid has biomimetic structures of natural islets and maintain cell-cell interactions, 3D spheroid culture leads a significant improvement of the maturity of IPCs.

INTRODUCTION: Osteonecrosis of the femoral head (ONFH) is a multifactorial disease that can cause femoral head collapse, pain, gait disorders. ONFH is common among young people in their 30s and 40s. In the clinic, although patients are diagnosed, 70%–80% of untreated patients experience femoral head collapse and have to undergo total hip arthroplasty. In the past decades, minimally invasive regenerative therapy has been desired for the early stages of ONFH. The purpose of this study was to evaluate the safety and clinical outcomes of rhFGF-2 gelatin hydrogel.

METHODS: Ten ONFH patients up to precollapse stage 2 underwent a single local administration of 800-μg rhFGF-2 gelatin hydrogel and were followed up for one year. Primary outcomes included adverse events and complications. Secondary outcomes included changes in Harris Hip Scores, VAS pain scores, UCLA scores, radiological changes as determined via X-ray, CT, and MRI images.

RESULTS & DISCUSSION: There were 14 adverse events (five patients). Patients completely recovered from all adverse events without problem. The surgery was performed with a minimally invasive technique (1 cm of skin incision), and walking was allowed from the day after surgery. Mean clinical scores improved significantly after four years compared with before surgery. There was only one case of femoral head collapse, and it had the greatest necrosis volume fraction and was considered to be in the early collapse stage at the time of operation. The other nine cases did not involve ONFH stage progression, and collapse was prevented. CT and MRI images confirmed bone regeneration in the ONFH.

CONCLUSIONS: Clinical application of rhFGF-2 gelatin hydrogel for precollapse stage of ONFH was feasible and safe. Our research is ongoing, further phase II multiple center study has been started in January 2016.

INTRODUCTION: Inflammation is a response to tissue damage and plays a key role in the initiation of tissue repair. When not resolved however, inflammation also impairs tissue repair. As a result of a traumatic cartilage injury, synovial inflammation occurs. The aim of our study was to investigate whether application of the anti-inflammatory drug triamcinolone acetonide (TAA) improves repair in a mouse cartilage defect model and whether timing of TAA administration is of influence.

METHODS: A full thickness cartilage defect was made in 10 weeks old male DBA/1 mice, a strain known to have cartilage repair capacity. One day or seven days after making the cartilage defect, 25 µg of TAA or saline was administered intra-articularly (4 groups, of 11 mice per group). Eight weeks after creation of the cartilage defect, the experiment was terminated. Knee joints were processed for histological analysis of the synovial thickness and filling of the cartilage defect.

RESULTS & DISCUSSION: Twelve out of 22 of the TAA-treated mice had patella dislocations, versus 3/22 (p<0.05) of the saline-treated mice. These mice were excluded from cartilage and synovium analysis. TAA significantly inhibited cartilage defect repair. Control mice that received saline injection demonstrated good defect filling of 83% ± 23% or 90% ± 7% in the animals treated at day 1 and week 1 respectively. In the mice that received TAA 1 day after making the defect, 76% ± 8% of the defect area was filled. In mice that received TAA 1 week after making the defect, 67% ± 15% of the defect area was filled (Figure 1, left). Synovial thickness had the tendency to be decreased in response to intraarticular TAA injection, albeit not statistically significant (Figure 1, right).

CONCLUSIONS: TAA is known to inhibit connective tissue growth, especially after damage, which most likely contributed to the increase in dislocations and the inhibition of cartilage repair, despite its anti-inflammatory properties and application as intra-articular analgesic. Dislocations and inhibition of cartilage repair were independent of the timing of administration. This warrants further investigation into targeted delivery of the TAA, to prevent the negative effects on cartilage regeneration.

Figure 1: left: Percentage area of the defect filled 8 weeks after making the cartilage defect in response to TAA administration. Right: Synovial thickness at week 8 in response to TAA treatment.
Elastin-like-recombimere hydrogel as a platform for lung regeneration

INTRODUCTION: Chronic obstructive pulmonary disease (COPD) is a world-wide health problem, where the tissue is gradually degraded leading to emphysema and loss of tissue integrity [1]. Our goal is to improve regeneration of the damaged tissue by inserting a cell-instructive biomaterial with the ability to activate regeneration in the border zone between destroyed areas and remains of healthy tissue in COPD. Elastin-like Recombinamer (ELR) hydrogels is a new type of biomaterial that have proved to have excellent biocompatibility properties [2]. In addition, the hydrogel has the possibility to add functionality by incorporating factors to guide the production and migration of cells.

METHODS: ELR is a two-part solution, which is a liquid at 4°C and solidifies at 37°C. The ELRs are modified so that one part has an alkyn modification while the second part has an azide modification. When these two parts are mixed at 4°C the alkyn reacts with the azide and creates a covalent bond and a hydrogel is formed. To be able to have a uniform dispersion of human fetal lung fibroblast (HFL1), cells in the hydrogel are mixed with the alkyn part before being mixed with the azide. Cells were then grown for 3 days and evaluated according to morphology and viability. As an alternative to the hydrogel conformation, an ELR-based cryogel was created by forming the hydrogel in subzero temperatures, which creates macro pores inside a conventional hydrogel.

RESULTS & DISCUSSION: HFL1 cells which were grown in the ELR hydrogel showed more in vivo like morphology as well as being uniformly dispersed throughout the hydrogel as shown in Figure 1 compared to cells cultured on top of the hydrogel. A cryogel with large interconnected pores, a structure closely resembling the distal lung tissue, was formed.

CONCLUSIONS: The data showed that an ELR-based hydrogel is a promising synthetic scaffold for lung tissue engineering, mimicking the 3D environment of the extracellular matrix. Work is now being undertaken to add functionality to the scaffold, to incorporate cytokines as well as growth factors into the hydrogel to be able to steer and differentiate cells into the desired state.

INTRODUCTION: The musculoskeletal diseases (MSDs) are the most common cause of severe long-term pain and physical disability affecting bones, muscles, cartilage, tendons, ligaments and joints. The recent advent of human induced pluripotent stem cells (iPSCs) provides an extensive opportunity to create human-specific models of MSDs. Moreover, human iPSC-based autologous transplantation is considered to be future breakthrough in the field of regenerative medicine.

METHODS: Since successful reprogramming of somatic cells to a pluripotent state by transient expression of four transcription factors (Oct4, Sox2, Klf4, and c-myc) was achieved for the first by Dr. Yamanaka and colleagues [1], the field has rapidly moved forward in order to reduce insertional mutation risks associated with viral delivery methods. The various non-viral approaches represent use of plasmid/episomal/minicircle vectors, direct protein/microRNA delivery and small molecules.

RESULTS & DISCUSSION: One of the major advantages of iPSCs is the ability to create specific MSD models to study their pathophysiology, such as fibrodysplasia ossificans progressiva, Duchene muscular dystrophy, osteosarcoma, Marfan syndrome, autosomal recessive osteopetrosis, etc. Moreover, there have been published various studies demonstrating successful bone, cartilage and muscle repair by iPSC-derived osteo/chondro–blasts and muscle cells, in vitro and in vivo [2][3]. However, the differentiation process of iPSCs into desired cell type remains time-consuming and quite difficult regarding proper cell maturation and purification.

CONCLUSIONS: The accessibility and therapeutic potential of patient’s own genetically corrected (CRISPR/Cas9) iPSCs provides a powerful tool for future cell-based regenerative medicine including bone, cartilage and muscle reconstruction. However, there is need for further research focusing on high quality control testing of iPSCs at different levels of their generation to eliminate the risk of tumor formation.
