Abstract

An MDA design approach should be able to accommodate designs at different levels of platform-independence. We have proposed a design approach previously (in [2]), which allows these levels to be identified. An important feature of this approach is the notion of abstract platform. An abstract platform is determined by the platform characteristics that are relevant for applications at a certain level of platform-independence, and must be established by considering various design goals. In this paper, we define a framework that makes it possible to use RM-ODP concepts in our MDA design approach. This framework allows a recursive application of the computational viewpoint at different levels of platform-independence. This is obtained by equating the RM-ODP notion of infrastructure to our notion of abstract platform.

1. Introduction

A current trend in the development of distributed applications is to separate their technology-independent and technology-specific aspects, by describing them in separate models. The most prominent development in this trend is the Model-Driven Architecture (MDA) [12, 15] development. A common pattern in MDA development is to define a platform-independent model (PIM) of a distributed application, and to apply (parameterised) transformations to this PIM to obtain one or more platform-specific models (PSMs). The main benefit of this approach stems from the possibility to derive different alternative PSMs from the same PIM depending on the target platform, and to partially automate the model transformation process and the realization of the distributed application on specific target platforms.

The concept of platform-independence plays a central role in MDA development. We believe that platform-independence can only be defined once a set of target platforms is known, such that their general capabilities and their irrelevant technological and engineering details can be established. This leads to the observation that there can be several PIMs, possibly at different abstraction levels, depending on whether one wants to consider different sets of target platforms. Another observation is that different application characteristics or different sets of target platforms generally lead to different types of (intermediate) models, design structures or patterns, and model transformations. These observations have motivated our investigations into what types of models can be useful in the MDA development trajectory, how these models are related, and which criteria should be used for their application. Some of the results of these investigations have been presented earlier in [2], where we have proposed an MDA design trajectory that accommodates designs at different levels of platform-independence.

An important feature of this approach is the notion of abstract platform. An abstract platform defines an acceptable or, to some extent, ideal platform from an application developer's point of view; it represents the platform support, as comprehensive and direct as possible, that is assumed by the application developer at some point in (the platform-independent phase of) the design trajectory. Alternatively, an abstract platform defines characteristics that must have proper mappings onto the set of concrete target platforms that are considered for an MDA design process, thereby defining the level of platform-independence for this particular process. Defining an abstract platform forces a designer to address two conflicting goals: (i) to achieve platform-independence, and (ii) to reduce the size of the design space explored for platform-specific realization.

Any design trajectory that is intended to be successfully applied in practice should be supported by suitable design concepts. In this paper we define a framework that makes it possible to use RM-ODP concepts in our MDA design trajectory. This is obtained by equating the RM-ODP notion of infrastructure to our notion of abstract platform. This framework allows a recursive application of the computational viewpoint at different levels of platform-independence.

This paper is further structured as follows: section 2 reviews the notions of platform-independence and abstract platform as adopted in this paper, section 3 discusses the RM-ODP concepts that are of particular relevance to our work, section 4 applies these concepts in our MDA design trajectory, and section 5 discusses some related work. Finally, section 6 presents some conclusions and open issues.

2. Platform notions

Platform-independence [15] is a quality of a model that relates to the extent to which the model abstracts from the characteristics of particular technology platforms. For the purpose of this paper, we assume that distributed applications are ultimately realized in some specific object- or component-middleware technology, such as CORBA/CCM [13, 14], .NET [11], and Web Services [20, 21]. Hence, platform corresponds ultimately to some specific middleware technology.

Currently, a large number of middleware platforms are available (a small sample of these can be found in the latest proceedings of the ACM/USENIX Middleware conference [6]). Different middleware platforms provide different levels of support for applications. For example, there are platforms that offer confidentiality for distributed interactions, that implement transparent load-balancing mechanisms, or that provide some capabilities for dynamic upgrade of application components. Platforms may also differ in the interaction patterns they support, such as *request/response*, *message passing*, *message queues* and group communication mechanisms. As a consequence, the design of an application in terms of a particular middleware platform is *platform-specific*, since: (i) the design depends on particular technological conventions adopted by the middleware platform; (ii) the structure of the application depends on the set of interaction patterns supported by the platform; and (iii) the functionality addressed at application level depends on the services provided by the platform.

2.1. Levels of platform-independence

Model reusability with respect to platforms, can be obtained by making these models platform-independent. Ideally, one could strive for PIMs that are absolutely neutral with respect to all different classes of middleware platforms. This is possible for models in which the characteristics of supporting infrastructure are irrelevant, such as, e.g., conceptual domain models [4] and ODP Enterprise Viewpoint models [9] (which can be considered Computation Independent Models [15] in MDA terms). However, along a development trajectory, when system architecture is captured, different sets of platform-independent modelling concepts may be used, each of which is adequate only with respect to specific classes of target middleware platforms. This leads to the observation that there can be several PIMs, including various levels of platform-independence, to be identified by a designer.

Figure 1 illustrates a possible hierarchy of models at different levels of platform-independence. In this figure, a highly abstract and neutral PIM is depicted at the highest level of platform-independence. An example of this type of PIM is the specification of the service of a groupware application. A service is a design that defines the observable behaviour of a system without unnecessarily constraining the system's internal structure. Therefore, the service concept can be used to describe the system without imposing the support provided by a particular concrete middleware platform. PIMs at a lower level of platform-independence are means to facilitate the mapping onto two particular classes of middleware platforms, namely RPC object-based and message-oriented platforms, respectively.

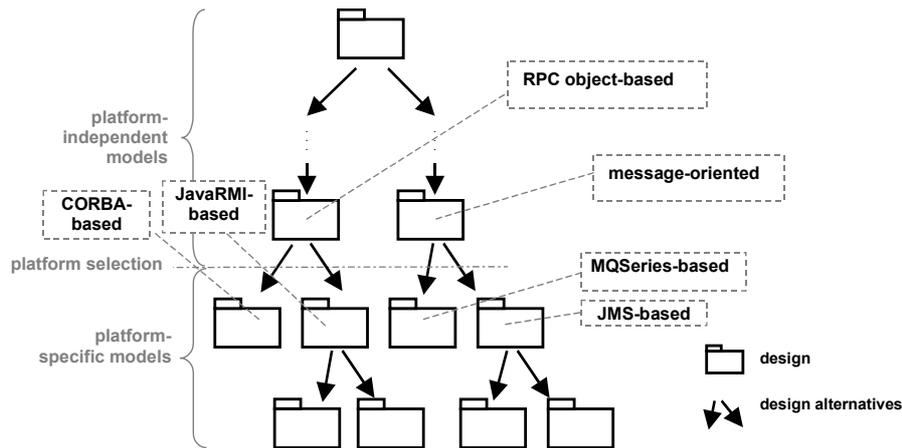

Figure 1 Models at different related levels of platform-independence

When different levels of platform-independence are necessary, they must be carefully identified. We propose to make this identification an explicit step in MDA development. We introduce the notion of abstract platform in order to assist a designer in this step.

2.2. Abstract platform

An abstract platform is determined by the platform characteristics that are relevant for applications at a certain platform-independent level. For example, if a platform-independent design contains application parts that interact through operation invocations, then operation invocation is a characteristic of the abstract platform. Capabilities of a concrete platform are used during platform-specific realization to support this characteristic of the abstract platform. For example, if CORBA is selected as a target platform, this characteristic can be mapped onto CORBA operation invocations.

Characteristics of an abstract platform may be implied by the choice of design concepts used for describing the platform-independent model of a distributed application. These concepts are often implied by the adopted modelling language. For example, the exchange of “signals” between “agents” in SDL [10] may be considered to define an abstract platform that supports reliable asynchronous message exchange. These concepts may also be specializations of concepts from the adopted modelling language. This can be the case with UML, which is specialized in order to suit the needs of platform-independent modelling, e.g., as specified in the EDOC UML Profile [17].

Instead of implying an abstract platform definition from the adopted set of design concepts for platform-independent modelling, it may be useful or even necessary to define some characteristics of an abstract platform explicitly, resulting in one or more separate and thus reusable design artefacts. During platform-independent modelling, a pre-defined abstract platform model may be composed with the model of the distributed application. For example, while UML 2.0 does not support group communication as a primitive design concept, it is possible to specify the behaviour of a group communication sub-system in UML. This sub-system can be re-used in the design of a distributed application that requires group communication. Other examples of pre-defined artefacts that may be included in abstract platforms are the ODP trader [8] and the OMG pervasive services (yet to be defined [15]).

As we argue in the following sections, the RM-ODP computational viewpoint offers concepts that are useful for the specification of platform-independent designs. Our proposed framework accommodates the aforementioned approaches to defining abstract platforms.

3. RM-ODP in application design

The RM-ODP (Reference Model for Open Distributed Processing [8] is an ISO/ITU-T standard that provides a specification framework for distributed systems development based on the concept of *viewpoints*. For each viewpoint, a vocabulary and grammar is provided, defining a conceptual framework for specifications in that viewpoint. The use of different viewpoints in the design of complex systems is an accepted technique to achieve separation of concerns. This also has been reflected in standards such as, e.g., the IEEE 1471 [7].

The RM-ODP computational and engineering viewpoints are relevant to the purpose of our work since they focus on application and infrastructure concerns respectively. The main motivation for having

separate viewpoints for these concerns is the complexity of the functionality required to overcome problems related to distribution (e.g., remoteness, partial failures, heterogeneity) and to exploit distribution capabilities (e.g., to achieve performance and dependability). This functionality is usually associated with the infrastructure, so that application developers can focus on application functionality instead.

3.1. Concepts in the computational viewpoint

The computational viewpoint is concerned with the decomposition of a distributed application into a set of interacting objects, abstracting from the supporting distribution infrastructure. In contrast, the engineering viewpoint focuses on the infrastructure required to support distributed applications. It is concerned with distribution properties and mechanisms that are abstracted from in computational viewpoint specifications.

The concept of (distribution) transparency is important in the RM-ODP. Transparency is defined as the property of hiding from a particular user (or developer) the potential behaviour of some parts of a system [8]. In the context of the computational and engineering viewpoints, transparency is used to hide mechanisms that deal with some aspect of distribution. An example of distribution transparency is replication transparency, which hides the possible replication of an object at several locations in a distributed system. In the computational viewpoint, a single computational object would be represented, while this computational object may possibly correspond to several replica objects in the engineering viewpoint. The mechanisms necessary to ensure replica consistency and management are addressed in the engineering viewpoint, shielding the (computational viewpoint) designers from the burden of developing these mechanisms. Distribution transparency is selective in ODP: the Reference Model includes rules for selecting transparencies. Transparencies are constraints on the mapping from a computational specification to a specification that uses specific ODP functions and engineering structures to provide the required form of masking.

In the computational viewpoint, applications consist of configurations of interacting *computational objects*. A computational object is a unit of distribution characterized by its behaviour. A computational object is encapsulated, i.e., any change in its state can only occur as a result of an internal action or as a result of an interaction with its environment. An object is said to have *interfaces*, each of which expose a subset of the interactions of that object. Interaction between objects is only possible if a *binding* can be established between interfaces of these objects. The computational viewpoint supports arbitrarily complex bindings, through the concept of binding object, which represents the binding itself as a computational object. The behaviour of a binding object determines the interaction semantics they support. As with any other object, binding objects can be qualified by quality of service assertions that constrain their behaviour. The computational model does not restrict the types of binding objects, allowing various possible communication structures between objects to be defined [8].

3.2. The RM-ODP notion of infrastructure

In [4], Blair and Stefani have equated the boundary between the computational and the engineering viewpoints to the distinction between application and infrastructure: “It is important to realize that the boundary between the two viewpoints is fluid, depending on the level of the virtual machine offered by the system’s infrastructure. Some systems will provide a rich and abstract set of engineering objects whereas others will provide a more minimal set of objects leaving more responsibility of the applications developer.” Specifications in the computational viewpoint are, according to this interpretation, influenced by the level of support provided by the infrastructure. By setting the level of support provided by the infrastructure, one can refer to computational concerns and engineering concerns.

Equating infrastructure to predefined middleware platforms would lead us to the conclusion that computational specifications are directly influenced by the level of support provided by a selected middleware platform. Computational specifications would therefore be, to some extent, platform-specific. In this case, the separation of computational and engineering concerns would be identical to the separation between application and middleware platform concerns. The reusability of a computational viewpoint specification would be restricted by its dependence on platform characteristics. Furthermore, from the perspective of application developers, the separation of computational and engineering concerns would be implied by the availability of a software infrastructure. Therefore, we conclude that the motivation for the separation of computational and engineering concerns is predominantly bottom-up.

Another interpretation for the infrastructure assumed by the computational viewpoint is that of an ‘ideal infrastructure’. In this interpretation, the motivation for the separation of computational and engineering

concerns is predominantly based on the needs of the developer to handle the complexity of application and infrastructure separately, regardless of the availability of a software infrastructure. The engineering viewpoint offers the possibility for a designer to engineer the infrastructure explicitly. While this interpretation is ideal from the perspective of separation of concerns for the application developer, it does not leverage the reuse of middleware platforms, which would significantly improve the efficiency of the development process.

Table 1 summarizes the implications of the contrasting interpretations to infrastructure.

Table 1 Interpretations of infrastructure compared

Interpretation (infrastructure equals to)	Reuse of middleware	Separation of concerns	Platform-independence
Available middleware platform	Yes	Defined by target platform	Low
Required middleware platform (ideal from application point of view)	No explicit consideration	Defined by designer's needs; motivated by complexity in application design	High

We conclude that both interpretations above have limitations when applied in conjunction with the MDA approach, which inspired us to investigate an alternative.

4. RM-ODP infrastructure notion revisited

Committing to one of the previously discussed interpretations of infrastructure is undesirable for the adoption of computational viewpoint concepts in the MDA. It may lead to models at a low level of platform-independence, or it may lead to models which cannot be realized on existing middleware platforms. We propose to equate the term infrastructure, as used in RM-ODP, to our notion of abstract platform. This approach can be beneficial for distributed application development, so that a proper balance can be obtained between the following design goals:

- designers can use the separation of application and infrastructure concerns to cope with the complexity of distributed application design;
- middleware platforms can be reused to improve significantly the efficiency of distributed application development; and
- platform-independence can be obtained as a means to preserve investments in application development and withstand changes in technology.

A consequence of equating infrastructure to abstract platform is that computational viewpoint concepts can be used at different levels of platform-independence. The use of the same conceptual framework for different levels of platform-independence contributes to a seamless refinement between platform-independent and platform-specific models. This facilitates the definition of correctness relations or even automated transformations.

An abstract platform is defined in terms of the bindings supported, the transparencies supported, and the types of quality-of-service (QoS) constraints that may be applied to interface contracts. The use of binding objects may provide considerable flexibility to implementations of platform-independent models, since it is possible to provide innumerable different implementations of a binding object. In addition, there is considerable freedom in choosing mechanisms for obtaining a required transparency and satisfying QoS constraints.

At any point in a design trajectory, a mapping to a platform-specific realization may be defined, as long as: (i) the semantics for the original model is respected, as defined by the vocabulary and rules of the computational language; and (ii) quality characteristics of the realizations obtained through mappings are acceptable.

4.1. Example: simple conference application

In order to illustrate the use of computational viewpoint concepts along our model-driven design trajectory, let us consider a conference service that facilitates the interaction of users residing in different

hosts. Initially, the service designer describes the service solely from its external perspective, as a conference binding object, revealing its interfaces and relating interactions that occur at these interfaces. Figure 2 shows a snapshot of the conference application with three user objects fulfilling the role of conference participants and a user object fulfilling the role of conference manager. Since characteristics of the internal structure of the binding object are not revealed, the user objects are specified at a high level of abstraction. The abstract platform at this level of abstraction supports the interaction between user objects and the conference binding object. The interfaces are described in terms of the ODP concepts of operations and signals.

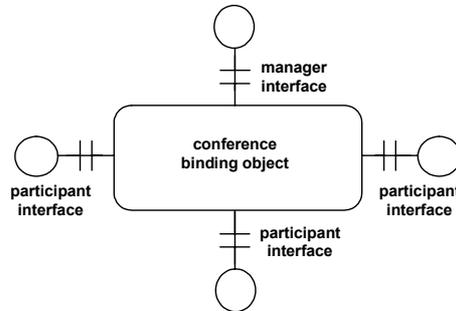

Figure 2 Snapshot of the conference application

This example reveals the flexibility of the specification at this level of platform-independence. The conference binding object may be further decomposed into a centralized or distributed, symmetric or asymmetric design, and different abstract platforms may be used to support the interactions of the objects that implement it. In fact, any number of recursive decompositions of the computational objects may be applied as necessary.

One possible way to proceed with design is shown in Figure 3. In this design, the internal structure of the conference binding object is revealed. The conference binding object is refined into a multicast binding object and computational objects interconnected through this binding. The abstract platform at this level of abstraction supports multicast bindings as prescribed in the definition of the service of the multicast binding object.

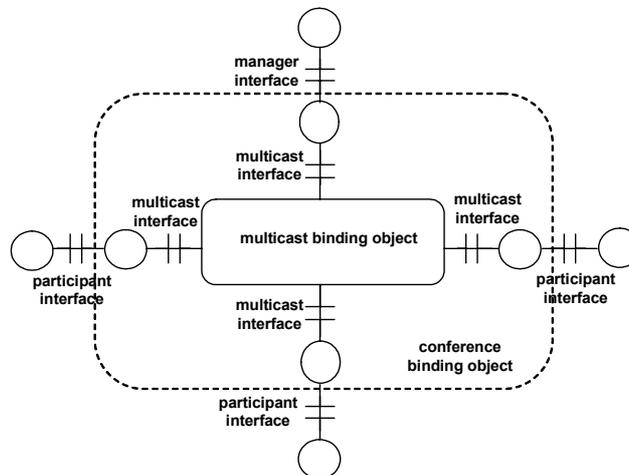

Figure 3 Revealing conference binding object decomposition

At this point in the design trajectory, a mapping can be used that realizes this design on top of a target platform that offers a multicast binding corresponding to that provided by the abstract platform. The engineering structures required to provide an adequate level of support are provided by the concrete platform. An alternative mapping could implement the multicast binding as a centralized object, realizing the interactions between the objects and the multicast binding object as distributed interactions. However, this alternative mapping may prove to be inadequate with respect to its quality-of-service characteristics, e.g., since a centralized implementation may fail to satisfy performance and scalability requirements.

When the target platform does not provide the required level of support, the design can be further detailed in an abstract platform at a lower level of platform-independence. The refinement depicted in Figure 4

assumes an abstract platform that only supports binary bindings of operational interfaces. This mapping differs from the previous design steps in that it does not consist solely of decompositions.

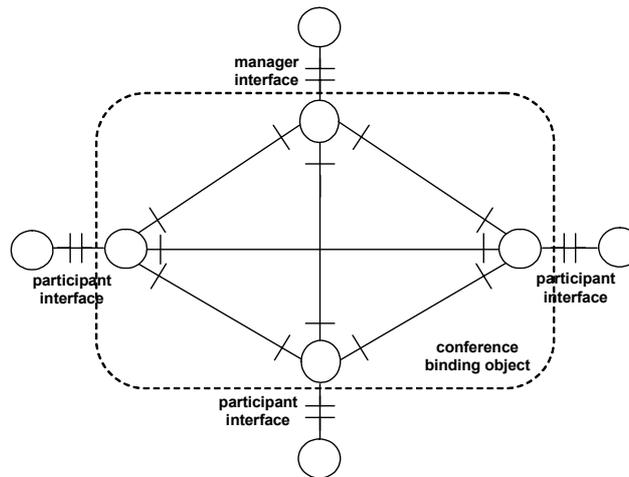

Figure 4 Possible mapping to replace multicast binding

The development trajectory that results from our approach as applied to the examples above is illustrated schematically in Figure 5.

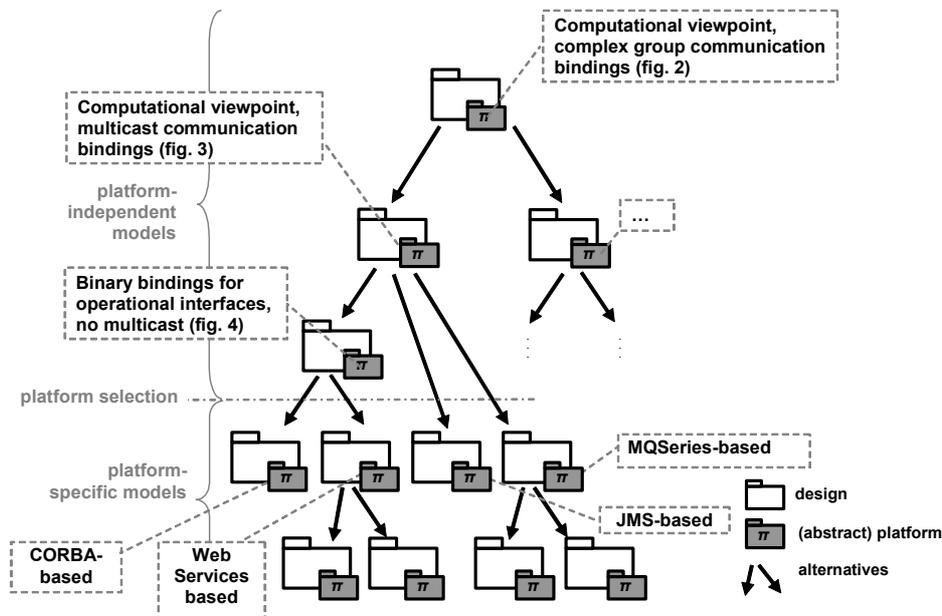

Figure 5 Models at related levels of platform-independence

4.2. Example: replication transparency

An example that reveals the role of transparencies in the design trajectory is presented in Figure 6(a). In this example, a client and a server object interact through an operation interface. A replication transparency schema is used to specify constraints on the availability and performance of the server object. Two different mappings of the source model (a) are depicted below. In Figure 6(b), a realization is obtained by mapping the source model directly to a platform that supports replication transparency, namely, Fault Tolerant CORBA. The infrastructure depicted is provided with this platform [13]. In Figure 6(c), a realization is obtained by mapping the source model into a target model that explicitly addresses the replication of the server object. A replication object is introduced to execute the replication function, delegating requests to the different replicas (for simplicity, we consider stateless server objects, and therefore we can omit extra interfaces required for checkpointing.). A possible realization of the application in Web Services [20, 21] is depicted schematically in Figure 6 (d).

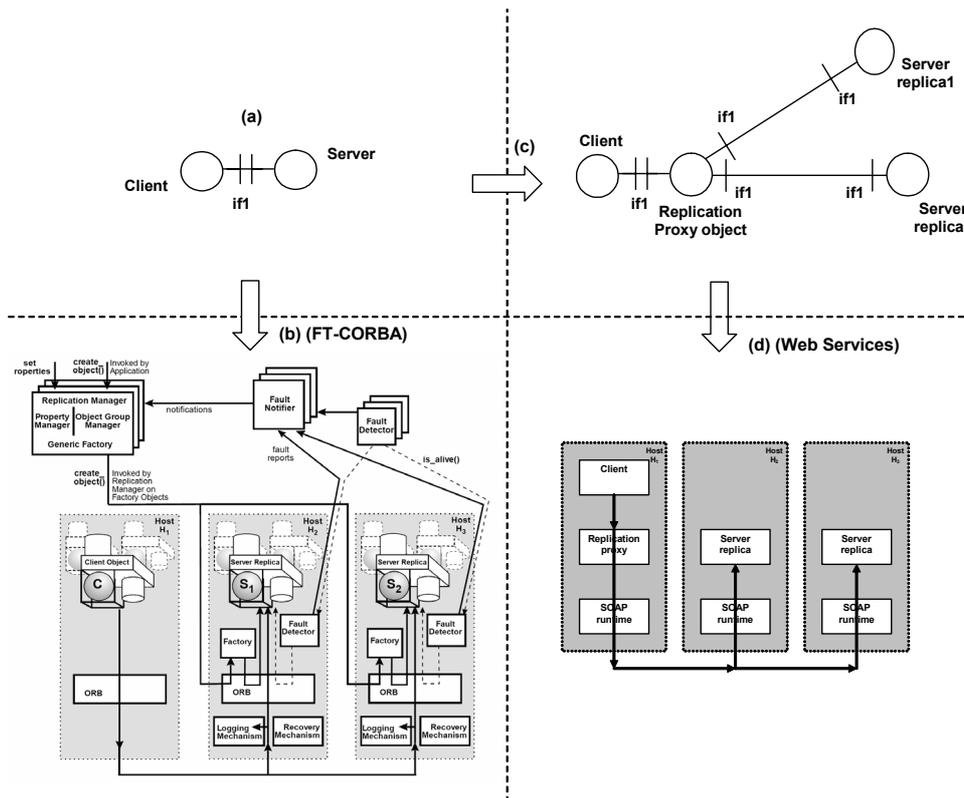

Figure 6 Alternative mappings for abstract platform with replication transparency

The list of transparencies defined in the RM-ODP is not exhaustive. In [3] we have discussed the role of replacement transparency in an MDA design trajectory.

5. Related work

The UML profile for EDOC [17] provides the notion of recursive component collaboration which corresponds to the notion of computational object in the RM-ODP. However, no notion of selective transparencies is provided in the EDOC profile. Furthermore there is no support for the specification of QoS constraints. The EDOC profile may be considered to define a single implicit abstract platform: interactions in the EDOC profile are always decomposed into asynchronous interactions through “Flow Ports”.

In [1], Akehurst et al. have focussed on the representation of the computational viewpoint concepts using MDA core technologies, namely UML and UML profiling. Putman [19] has also proposed some extensions to UML to accommodate the use of ODP design concepts. In contrast, in this paper, we investigate the role of ODP concepts with respect to design goals introduced by the use of platform-independent models. Both [1, 25] can be seen as complementary to the framework proposed in this paper, and the representations they propose may be applicable to the design trajectory we have discussed.

6. Conclusions

Ideally, a designer should be able to arbitrarily select distribution transparencies in the computational viewpoint, and have the mechanisms required by these transparencies addressed in reusable middleware platforms. This is not the case, however, since middleware platforms are a result of compromise and selection of generic capabilities.

The separation between application and middleware platform concerns is therefore not sufficient to cope with the separation of concerns in complex distributed systems, particularly since application requirements are so diverse. Furthermore, applications described from a platform-specific viewpoint cannot be reused for different platforms.

The separation of RM-ODP computation and engineering viewpoints provides a means to separate between application and infrastructure concerns. This separation can be explored along a model-driven design trajectory, introducing infrastructure concerns progressively towards realizations on concrete

infrastructures, i.e., available middleware platforms. We have demonstrated that the computational viewpoint concepts can be suitable for our design trajectory if we equate the RM-ODP notion of infrastructure to that of abstract platform. An abstract platform is defined in terms of the bindings supported, the transparencies supported, and the types of QoS constraints that may be applied to interface contracts. Characteristics of this abstract platform must be established by considering the different design goals.

There is no obvious distinction between platform-independent and platform-specific concerns, and no general rule to decide what is platform-independent. The needs to reuse platforms and to handle design complexity must drive a designer's decision on the boundaries. Defining an abstract platform brings attention to *balancing* between: (i) platform-independent modelling, and (ii) platform-specific realization. Using a well-founded reference model to refer to abstract platform enables agreement on the concepts for the description of abstract platforms, and may prove to be an initial step towards a comprehensive abstract platform reference architecture.

The notions of platform-independence and abstract platform should be used *judiciously*. The costs of maintaining different levels of platform-independence must not outweigh the benefits of the reuse of platform-independent models. Evaluating these costs in the beginning of a design trajectory is not straightforward, since the benefits of the separation must be considered on the long run. This evaluation remains an open issue.
