Abstract. With their increasing popularity in cryptosystems, biometrics have attracted more and more attention from the information security community. However, how to handle the relevant privacy concerns remains to be troublesome. In this paper, we propose a novel security model to formalize the privacy concerns in biometric-based remote authentication schemes. Our security model covers a number of practical privacy concerns such as identity privacy and transaction anonymity, which have not been formally considered in the literature. In addition, we propose a general biometric-based remote authentication scheme and prove its security in our security model.

1 Introduction

Privacy has become an important issue in many aspects of our daily life, especially in an era of networking where information access may go far beyond our control. When sensitive information such as biometrics is used, the privacy issues become even more important because corruption of such information may be catastrophic for the relevant applications. In this paper we focus on the issue of handling the privacy concerns in remote biometric-based authentication schemes.

1.1 Related Work

Biometrics, such as fingerprint and iris, have been used to a higher level of security in order to cope with the increasing demand for reliable and highly-usable information security systems, because they have many advantages over typical cryptographic credentials. For example, biometrics are believed to be unique, unforgeable, non-transferable, and they do not need to be stored. One of the most important application areas is biometric-based authentication schemes, where an authentication is simply a comparison between a reference biometric template

* This work is partially supported by French ANR RNRT project BACH.

** The work was done when the author worked as a postdoc researcher at École Normale Supérieure.

and a new template extracted during the authentication process. Note that, depending on the type of biometrics, comparison may mean image matching, binary string matching, etc.

Despite of its advantages, in practice, there are some obstacles in a wide adoption of biometrics.

First, biometrics are only approximately stable over the time, therefore, they cannot be directly integrated into most of the existing systems. To address this issue, error-correction concept is widely used in the literature (e.g. [3,4,8,10,11,18,19,25,29]). Employing this concept, some intermediate information (referred to as helper data in some work) is firstly generated based on a reference biometric template, and later, a newly-extracted template could help to recover the reference template or some relevant information if the distance between the templates is small enough (depending on the type of biometrics). Instead of employing this concept, a number of authors also suggest to compare biometric templates directly (e.g. [1,12,34]). Atallah *et al.* [1] propose a method, in which biometric templates are treated as bit strings and subsequently masked and permuted during the authentication process. Du and Atallah [12,34] investigate a number of biometric comparison scenarios by employing secure multiparty computation techniques. Schoenmakers and Tuyls [27] propose to use homomorphic encryption schemes for biometric authentication schemes by employing multi-party computation techniques.

Second, biometrics are usually regarded to be sensitive because they uniquely identify an individual. The sensitivity of biometrics lies in the fact that disclosure of biometrics in a certain application leads to the disclosure of the true identity of the involved users in this application. In addition, if the same type of biometrics of a user is used in two applications, then there is an undeniable link for the user's activities in both applications. Nonetheless, it is worth stressing that biometrics are normally considered to be public information. In [20,28,29,31,33], the authors attempt to enhance privacy protection in biometric authentication schemes, where the privacy means that the compromise of the database will not enable the adversary to recover the biometric template. Ratha, Connell, and Bolle [2,24] introduce the concept of *cancelable biometrics* in an attempt to solve the revocation and privacy issues related to biometric information. Ratha *et al.* [23] intensively elaborate this concept in the case of fingerprint-based authentication systems. Recently, Bringer *et al.* [5,6] propose a number of biometric-based authentication protocols which protect the sensitive relationship between a biometric feature and relevant pseudorandom username.

Practical concerns, security issues, and challenges about biometrics have been intensively discussed in the literature (e.g. [2,17,21,24,26,32]). Tuyls, Skoric, and Kevenaar [30] present a summary of cryptographic techniques for dealing with biometrics.

1.2 Motivation and Contributions

The stability problem concerned with biometric measurements has been paid pretty much attention and investigated very well at this moment. However,

privacy issues concerned with biometrics have not been understood well. With respect to biometric-based authentication schemes, we do not have a general formalization of privacy concerns based on a clear system structure. In practice, privacy may mean much more than the adversary cannot recover the user's biometric template. For instance, a user may also want the relationship between its biometric template and username to remain secret in a service, where the user uses a personalized (pseudorandom) username instead of his true name. This requirement might become much stronger if the user wants to multiple registrations under different usernames at the service provider.

In the rest of this paper, we consider the following scenario for biometric-based authentication schemes: Suppose a human user registers at a service provider to consume some service and would like to authenticate himself to the service provider using his biometric (say, his iris). Typically, the user will choose a personalized username and register his reference biometric information under this username. In order to authenticate himself to the service provider, the user presents his username and some fresh biometric information, and then the service provider will perform a matching between the reference biometric information and the fresh biometric information. The contributions of this paper can be summarized as follows.

First, we propose a new system structure for biometric-based remote authentication schemes. In the new structure, there are four types of components, including human user, sensor client, service provider, and database. There are two motivations for us to assume sensor client and service provider to be independent, which means the service provider does not control the sensor client.

1. One is to protect human users' privacy against a malicious service provider. If a malicious service provider controls the sensor client, then it can easily obtain human users' biometric information and potentially manipulate the information.
2. The other is based on the fact that human users may wish to access the service provider wherever they are. In this case, it is natural to make the assumption that sensor client could be provided by another party which has business agreement with the service provider.

Different from any previous system, the database is assumed to be independent from the service provider and serve as a secure storage for biometric information. The motivations for the detachment are as follows.

1. The first is that a user may not trust a service provider to store his biometric template regardless of the transformation which might be applied to the template.
2. The second is that the service provider's access to the biometric information can be minimized, so is the database's access. This structure makes it possible to protect human users' privacy against a malicious service provider or a malicious database. Under the traditional structure, where the service

provider controls the database, we do not see how to achieve our privacy goal¹.

3. The third is that, in practice, the service provider has avoided the responsibility for storing biometric templates. As data breaches for service providers are reported more and more frequently nowadays, the need for the separation becomes stronger and stronger.

With respect to the new structure, we formalize the following attributes related to privacy concerns which have not been formally considered in the literature.

- The security for private relationship between personalized username and biometric template is defined to be an attribute *identity privacy*.
- The security for user’s transaction statistics is defined to be an attribute *transaction anonymity*.

Note that, for non biometric-based (authentication) schemes, the requirement of identity privacy might not be as significant as in our case because cryptographic credentials are not bound to an individual permanently.

Second, we propose a general biometric-based remote authentication scheme by employing a Private Information Retrieval (PIR) protocol [7,9,15] and the ElGamal public-key encryption scheme [13]. The security of the scheme is based on the semantic security of ElGamal, namely the DDH assumption. Instead of ElGamal, other homomorphic encryption schemes can also be used for the same purpose but the computational load will stay in a similar level. Our proposal is not focused on a specific biometric, but rather on such type of biometrics that can be represented as binary strings in the Hamming space and authentication can be done through a binary string matching. For example, iris is one type of such biometrics [16]. For other biometrics, how to construct a secure authentication scheme in our security model remains as an open problem.

1.3 Organization

The rest of the paper is organized as follows. In Section 2 we provide some preliminary definitions. In Section 3 we provide the security and privacy definitions for biometric-based remote authentication schemes. In Section 4 we present a new biometric-based remote authentication scheme. In Section 5 we provide security analysis for the new scheme in our security model. In Section 6 we conclude the paper.

2 Preliminary Definitions

2.1 The System Structure

In the new system structure for biometric-based authentication schemes, we consider four types of components.

¹ Especially, applying a one-way function to the biometric template will not be enough to achieve our privacy goal.

- Human user, which uses his biometric to authenticate himself to a service provider.
- Sensor client, which captures the raw biometric data and extracts a biometric template, and communicates with the service provider.
- Service provider, which deals with human user’s authentication request by querying the database.
- Database, which stores biometric information for users, and works as a biometric template matcher by providing the matching service to the service provider.

Remark 1. Different from the local authentication environment, sensor client and service provider are assumed to be independent components in our structure. We consider this to be an appropriate assumption in the remote authentication environment, where human users access the service provider through sensor clients, which are not owned by the service provider but have a business agreement with the service provider.

Remark 2. In practice, there might be only very few organizations that can be trusted by human users to store their biometric information though they may want to use their biometrics for the authentication purpose at many service providers. Therefore, in practice we suggest an scenario like that of Single Sign-On systems [22], where biometric information for all service providers are centralizedly stored and managed. In addition, in our security model the centralized database won’t be a bottleneck in the sense of security.

For the simplicity of description, in the following discussions, we assume N users U_i ($1 \leq i \leq N$) register at a service provider \mathcal{S} , these users authenticate themselves through a sensor client \mathcal{C}^2 , and the database is denoted as \mathcal{DB} . Moreover, we would expect users to conduct their authentication services at different service providers while registering their biometric templates in the same (trusted) database.

2.2 The Authentication Workflow

Like most existing biometric-based cryptosystems, we also assume that a biometric-based authentication scheme consists of two phases: an enrollment phase and a verification phase.

1. In the enrollment phase, user U_i registers his reference biometric information, which is computed based on his reference biometric template b_i , at the database \mathcal{DB} and his personalized username ID_i at the service provider \mathcal{S} . Note that a human user may have multiple registrations at the same service provider.
2. In the verification phase, user U_i issues an authentication request to the service provider \mathcal{S} through the sensor client \mathcal{C} . \mathcal{S} matches U_i ’s biometric templates with help from the database \mathcal{DB} .

² In practice, there may be a number of sensor clients for human users to access the service provider, but this simplification will not affect our security result.

2.3 Assumptions and Trust Relationships

We make the following assumptions.

1. Biometric Distribution assumption: Let H be the distance function in a metric space (in this paper, we assume it to be Hamming space). Suppose b_i and b_j are the reference biometric templates for Alice and Bob, respectively. There is a threshold value λ , the probability that $H(b_i, b'_j) > \lambda$ is close to 1 and the probability that $H(b_i, b'_i) \leq \lambda$ is close to 1, where b'_i and b'_j are the templates captured for Alice and Bob at any time.
2. Liveness assumption: We assume that, with a high probability, the biometric template captured by the sensor is from a live human user. In other words, it is difficult to produce a fake biometric template that can be accepted by the sensor.
3. Security link assumption: The communication links between components are protected with confidentiality and integrity. In practice, the security links can be implemented using a standard protocol such as SSL or TLS.

The biometric distribution and the liveness assumptions are indispensable for most of biometric-based cryptosystems and they are considered as a prerequisite for the adoption of biometrics. Note that biometrics are public information, additional credentials are always required to establish security links in order to prevent some well-known attacks (e.g. replay attacks). Therefore, the security link assumption is indeed also assumed in most cryptosystems, though it is not as standard as others.

In a biometric-based authentication system, we assume the following trust relationships.

1. Sensor client is always honest and trusted by all other components. By assuming this trust relationship, the liveness assumption is extended from sensor client to service provider in the following sense: when the service provider receives a username and some fresh biometric information, it can confirm with a high probability that the the fresh biometric information is extracted from a human user which has presented the username to the sensor client.
2. With respect to authentication service, service provider is trusted by human users to make the right decision, and database is trusted by human users and the service provider to store and provide the right biometric information. Only an outside adversary may try to impersonate an honest human user.
3. With respect to privacy concerns, both service provider and database are assumed to be malicious which means they may deviate from the protocol specification, but they will not collude. In reality, an outside adversary may also pose threats to the privacy concerns, however, it has no more advantage than a malicious system component.

3 Security Model for Biometric-Based Authentication

We first describe some conventions for writing probabilistic algorithms and experiments. The notation $x \stackrel{R}{\leftarrow} S$ means x is randomly chosen from the set S .

If \mathcal{A} is a probabilistic algorithm, then $\mathcal{A}(\text{Alg}; \text{Func})$ is the result of running \mathcal{A} , which can have any polynomial number of oracle queries to the functionality Func , interactively with Alg which answers the oracle queries issued by \mathcal{A} . For the clarity of description, if an algorithm \mathcal{A} runs in a number of stages then we write $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2, \dots)$. As a standard practice, the security of a protocol is evaluated by an experiment between an adversary and a challenger, where the challenger simulates the protocol executions and answers the adversary's oracle queries. Without specification, algorithms are always assumed to be polynomial-time and the security parameter is assumed to be ℓ .

Specifically, in our case, there are two functionalities **Enrollment** and **Verification**, where **Enrollment** can be initiated only once to simulate the enrollment phase and **Verification** can be initiated for any user to start an authentication session for any polynomial times. Without loss of generality, if **Verification** is initiated for U_i , we write $\text{Verification}(i)$.

In addition, we have the following definitions for negligible and overwhelming probabilities.

Definition 1. *The function $P(\ell) : \mathbb{Z} \rightarrow \mathbb{R}$ is said to be negligible if, for every polynomial $f(\ell)$, there exists an integer N_f such that $P(\ell) \leq \frac{1}{f(\ell)}$ for all $\ell \geq N_f$. If $P(\ell)$ is negligible, then the probability $1 - P(\ell)$ is said to be overwhelming.*

3.1 Soundness and Impersonation Resilience

Definition 2. *A biometric-based authentication scheme is defined to be sound if it satisfies the following two requirements:*

1. *With an overwhelming probability, the service provider will accept an authentication request in the following case: sensor client sends (ID_i, b) in an authentication request, where $H(b, b_i) \leq \lambda$ and b_i is the reference template registered for ID_i .*
2. *With an overwhelming probability, the service provider will reject an authentication request in the following case: sensor client sends (ID_i, b) in an authentication request, where $H(b, b_i) > \lambda$ and b_i is the reference template registered for ID_i .*

If b , where $H(b, b_i) \leq \lambda$, is extracted from a user different from the user registered under b_i , then we say false accept occurs. Otherwise, if b , where $H(b, b_i) > \lambda$, is extracted from the user registered under b_i , then we say false reject occurs. From a cryptographic point of view, the false reject rate and the false accept rate may be very high. However, this issue is irrelevant to our privacy concerns, hence, how to handle them is beyond the scope of our paper.

For authentication schemes, impersonation resilience should be the primary goal, nonetheless, under the security link assumption and the liveness assumption, soundness implies impersonation resilience in our case so that we omit the formalization.

3.2 Identity Privacy

In practice, a malicious service provider or a malicious database may try to probe the relationships between personalized usernames and biometric templates, though they do not need such information in order to make the system work. Informally, the attribute identity privacy means that, for any personalized username, the adversary knows nothing about the corresponding biometric template. It also implies that the adversary cannot find any linkability between registrations in the case that the same human user has multiple registrations at the service provider.

Definition 3. *A biometric-based authentication scheme achieves identity privacy if $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$ has only a negligible advantage in the following game, where the advantage is defined to be $|\Pr[e' = e] - \frac{1}{2}|$.*

$$\text{Exp}_A^{\text{Identity-Privacy}} \left\{ \begin{array}{ll} (i, ID_i, b_i^{(0)}, b_i^{(1)}, (ID_j, b_j) (j \neq i)) \leftarrow \mathcal{A}_1(1^\ell) & \\ b_i = b_i^{(e)} \xleftarrow{R} \{b_i^{(0)}, b_i^{(1)}\} & \\ \emptyset \leftarrow \text{Enrollment}(1^\ell) & \\ e' \leftarrow \mathcal{A}_2(\text{Challenger}; \text{Verification}) & \end{array} \right.$$

Note that the symbol \emptyset means that there is no explicit output (besides the state information) for the adversary. In the experiment, presumably, the adversary \mathcal{A}_2 will obtain the corresponding information³ from the challenger. The attack game can be informally rephrased as follows:

1. The adversary \mathcal{A}_1 generates N pairs of username and relevant biometric template, but provides two possible templates $(b_i^{(0)}, b_i^{(1)})$ for ID_i .
2. The challenger randomly chooses a template $b_i^{(e)}$ for the username ID_i , and simulates the enrollment phase to generate the parameter for the sensor client, the service provider, and the database.
3. The adversary \mathcal{A}_2 can initiate any (polynomial) number of protocol instances for the verification protocol, and terminates by outputting guess e' .

In this definition (and Definition 4), the adversary can freely choose the username and biometric template pairs for the enrollment phase, therefore, it models the security for any type of biometric regardless of its distribution in practice. It is worth stressing that, if a scheme achieves identity privacy, then neither a malicious service provider or a malicious database (or an outside adversary which has compromised any of them) can recover any registered biometric template.

As to our knowledge, none of the existing biometric-based authentication schemes (including those in Section 1) achieve identity privacy under our definition. Informally, these scheme suffers from the following vulnerability: Suppose that human users use their iris to authenticate themselves to a service provider \mathcal{S} .

³ The information refers to that of the malicious component at the end of the enrollment phase.

If \mathcal{S} is malicious (or a hacker which has compromised the biometric database of \mathcal{S}), then it can easily determine whether a human being, say Alice, has registered.

3.3 Transaction Anonymity

Since the database is supposed to store biometric information, therefore, it might obtain some transaction statistics about the service provider and registered human users. Informally, the attribute transaction anonymity means that, for every query issued by the service provider, a malicious database knows nothing about which user is authenticating himself to the service provider.

Definition 4. *A biometric-based authentication scheme achieves transaction anonymity if an adversary $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3)$ has only a negligible advantage in the following game, where the advantage is defined to be $|\Pr[e' = e] - \frac{1}{2}|$.*

$$\mathbf{Exp}_A^{\text{Transaction-Anonymity}} \left| \begin{array}{ll} (ID_j, b_j)(1 \leq j \leq N) & \leftarrow \mathcal{A}_1(1^\ell) \\ \emptyset & \leftarrow \text{Enrollment}(1^\ell) \\ \{i_0, i_1\} & \leftarrow \mathcal{A}_2(\text{Challenger}, \text{Verification}) \\ i_e & \stackrel{R}{\leftarrow} \{i_0, i_1\} \\ \emptyset & \leftarrow \text{Verification}(i_e) \\ e' & \leftarrow \mathcal{A}_3(\text{Challenger}; \text{Verification}) \end{array} \right.$$

As the adversary is a malicious database, presumably the adversary \mathcal{A}_2 will obtain the corresponding information from the challenger. The attack game can be informally rephrased as follows:

1. The adversary \mathcal{A}_1 generates N pairs of username and relevant biometric template.
2. The challenger simulates the enrollment phase to generate the parameters.
3. The adversary \mathcal{A}_2 can then initiate any (polynomial) number of protocol instances for the verification protocol. At some point, \mathcal{A}_2 chooses two users U_{i_0}, U_{i_1} and asks the challenger to initiate an instance for the verification protocol.
4. The challenger chooses U_{i_e} and initiates an instance for the verification protocol.
5. The adversary \mathcal{A}_3 can continue to initiate any number of protocol instances, and terminates by outputting guess e' .

4 A General Biometric-Based Authentication Scheme

In this section we describe a general biometric-based authentication scheme, where the biometric template matching can be done through binary string comparison. We first describe the enrollment phase and the verification phase, and then provide some remarks.

4.1 The Enrollment Phase

In the enrollment phase, every component initializes its parameters as follows.

- \mathcal{C} generates a key pair (pk_c, sk_c) for a signature scheme (KeyGen, Sign, Verify) and publishes the public key pk_c . In addition, \mathcal{C} implements a $(\mathcal{M}, m, \tilde{m}, \lambda)$ -secure sketch scheme (SS, Rec) [11], where \mathcal{M} is the space of biometric template, m and \tilde{m} can be any values, and λ is the threshold value in the biometric distribution assumption described in Section 2.3.
- \mathcal{DB} generates an ElGamal key pair (pk_{db}, sk_{db}) , where $pk_{db} = (\mathbb{G}_{db}, q_{db}, g_{db}, y_{db})$, $y_{db} = g_{db}^{x_{db}}$, and $sk_{db} = x_{db}$, and publishes pk_{db} .
- \mathcal{S} generates an ElGamal key pair (pk_s, sk_s) , where $pk_s = (\mathbb{G}_s, q_s, g_s, y_s)$, $\mathbb{G}_s = \mathbb{G}_{db}$, $g_s = g_{db}$, $y_s = g_s^{x_s}$, and $sk_s = x_s$, and publishes pk_s .
- U_i generates his personalized username ID_i and registers it at the service provider \mathcal{S} , and registers B_i at the database \mathcal{DB} , where b_i is U_i 's reference biometric template and

$$\begin{aligned} B_i &= \text{Enc}((g_s)^{ID_s || ID_i || b_i}, pk_s) \\ &= (B_{i1}, B_{i2}) \end{aligned}$$

Note that B_i has two components since the encryption scheme is ElGamal. In addition, U_i (publicly) stores a sketch $sketch_i = \text{SS}(b_i)$.

4.2 The Verification Phase

If U_i wants to authenticate himself to the service provider \mathcal{S} through the sensor client \mathcal{C} , they perform as follows.

1. The sensor client \mathcal{C} extracts U_i 's biometric template b_i^* and computes the adjusted template $b'_i = \text{Rec}(b_i^*, sketch_i)$. If $\text{H}(b_i^*, b'_i) \leq \lambda$, \mathcal{C} sends $(ID_i, M_{i1}, M_{i2}, \sigma_i)$ to the service provider \mathcal{S} , where

$$\begin{aligned} X_i &= \text{Enc}((g_s)^{ID_s || ID_i || b'_i}, pk_s) \\ &= (X_{i1}, X_{i2}), \end{aligned}$$

$$M_{i1} = \text{Enc}(X_{i1}, pk_{db}), \quad M_{i2} = \text{Enc}(X_{i2}, pk_{db}),$$

$$\sigma_i = \text{Sign}(ID_s || M_{i1} || M_{i2}, sk_c).$$

Otherwise, \mathcal{C} aborts the operation.

2. \mathcal{S} first retrieves the index i for ID_i and then forwards $(M_{i1}, M_{i2}, \sigma_i)$ to the database \mathcal{DB} .
3. \mathcal{DB} first verifies the signature σ_i . If the verification succeeds, \mathcal{DB} decrypts M_{i1} and M_{i2} to recover X_i . For every $1 \leq \ell \leq N$, the database randomly selects $s_t \in \mathbb{Z}_{q_s}$ and computes $R_t = (X_i \odot B_\ell)^{s_t}$, where, for any integer x and two ElGamal ciphertexts (c_1, c_2) and (c_3, c_4) , the operator \odot is defined as follows: $((c_1, c_2) \odot (c_3, c_4))^x = ((\frac{c_1}{c_3})^x, (\frac{c_2}{c_4})^x)$.
4. The server runs a PIR protocol to retrieve R_i . If $\text{Dec}(R_i, sk_s) = 1$, \mathcal{S} accepts the request; otherwise rejects it.

4.3 Remarks on the Proposed Scheme

It is well known that, with ElGamal scheme, we need to encode the plaintext in a certain way in order to obtain semantic security, however, there is no encoding method which will fully preserve the homomorphic property. In our case, we set $\mathbb{G}_s = \mathbb{G}_{db}$ and $g_s = g_{db}$, so that all plaintexts are exponentiations of g_s and we avoid the encoding problem.

Under the original definition given in [11], a secure sketch scheme is typically used to preserve the entropy of the input and allow the reconstruction of the input in the presence of a certain amount of noise. In our case, we only need the second functionality, namely the secure sketch scheme is used to remove the noise in the fresh biometric template. Therefore, we allow the parameters m and \tilde{m} to be any values. The choice of λ depends on both the type of biometric and the underlying application's requirements on false accept and false reject rates.

User U_i does not need to register any information, either public or private, at the sensor client, though it need to store some public information, namely the secure sketch. The authentication is conducted through an exact equivalence comparison between the reference template and the adjusted fresh template (say, the output from the secure sketch scheme). As a result, we avoid the need to perform approximate biometric matchings on the service provider side and are able to use the underlying cryptographic techniques. This makes the scheme more scalable and flexible than other similar schemes. Compared with the existing remote authentication schemes (e.g. those in [3,4,8]), the proposed scheme demonstrates our concept of detaching biometric information storage from the service provider and shows a way to enhance human users' privacy in practice. In addition, our scheme also demonstrates a method to transform the existing schemes to satisfy our security definition, i.e. using a combination of plaintext equivalence test and PIR.

The computational complexity is dominated by that of the database \mathcal{DB} which has to perform $O(N)$ exponentiations, the sensor client needs to perform 6 exponentiations and sign one message for each authentication attempt, while the service provider only needs to decrypt one message (one exponentiation) to make a decision. In addition, there is some computational load in running the PIR protocol. The communication complexity is dominated by the PIR protocol. If it is instantiated to be the single-database PIR protocol of Gentry and Ramzan [14], then the communication complexity between the service provider and the database is $O(\ell + d)$, where d is the bit-length of an ElGamal ciphertext and $\ell \geq \log N$ is the security parameter.

5 Security Analysis of the Proposed Scheme

5.1 Soundness and Impersonation Resilience

From the biometric distribution assumption and the soundness of the secure sketch, it is straightforward to verify that the proposed authentication scheme is sound under Definition 2. In addition, U_i 's biometric templates b_i and b'_i are

encoded in the form $(g_s)^{ID_s || ID_i || b_i}$ and $(g_s)^{ID_s || ID_i || b'_i}$. Hence, if the entropy of the adopted biometric is high, then the service provider and the database, even if they collude, cannot recover the biometric templates based on the Discrete Logarithm assumption.

5.2 Security Proof for Identity Privacy

In the verification protocol, even if security sketch is adopted, it is not guaranteed that $b'_i = b_i$. Therefore, in the security proof, we assume that the difference pattern, i.e. the distribution of $b'_i - b_i \pmod q$, is denoted as *pattern_i*. In fact, the security results are independent from the difference patterns. Due to the page limit, the proofs for both lemmas will appear in the full version of this paper.

Lemma 1. *The proposed scheme achieves identity privacy against malicious \mathcal{S} , based on the semantic security of the ElGamal scheme and the existential unforgeability of the signature scheme.*

Lemma 2. *The proposed scheme achieves identity privacy against malicious \mathcal{DB} , based on the semantic security of the ElGamal scheme.*

5.3 Security Proof for Transaction Anonymity

We next show that the proposed scheme achieves transaction anonymity. The proof of this lemma will appear in the full version of this paper.

Lemma 3. *The proposed scheme achieves transaction anonymity against malicious \mathcal{DB} , based on the semantic security of the ElGamal scheme and the security (user privacy) of the PIR protocol.*

5.4 Further Remarks

In our security analysis, as to an outside adversary, we only considered the case where it has not compromised any system component. If the adversary has compromised the sensor client \mathcal{C} , then it may impersonate an honest user to the service provider if it obtains this user's biometric template (note that biometrics are public information). This is a common problem for many authentication systems, unless we adopt a tamper-resistant sensor client. If the adversary has compromised the service provider \mathcal{S} or the database \mathcal{DB} , then the identity privacy property is still preserved. A possible vulnerability when \mathcal{DB} is compromised is that it may be able to impersonate any user in the system by impersonating \mathcal{DB} to the service provider. Again, this is a common problem for most authentication systems, and one possible solution is to adopt a layered security design. For example, tamper-resistant hardware can be used for establishing communication links. Then, even if the adversary has compromised the database, the ciphertexts of biometric templates will not help him to impersonate any honest user.

6 Conclusion

In this paper we have proposed a specifically-tailored system structure and security model for biometric-based authentication schemes. In our security model, we describe two privacy properties, namely identity privacy and transaction anonymity, which are believed to be serious concerns because of the uniqueness of biometrics. We have also proposed a general authentication scheme which fulfills the security properties described in our security model. An interesting characteristic of our scheme is that, assuming biometric template and secure sketch to be public, a user does not need to store any private information and register any information at the sensor client. In addition, the security requirements on the secure sketch scheme can be greatly relaxed (entropy preservation is not required). As a further research direction, it is interesting to investigate more efficient solutions in our security model.
